Tubercle is an anatomicopathologic concept which, unless qualified, refers only to the typical, fully developed, mature tubercle; and does not refer to actual etiology or genesis. The typical mature tubercle is considered to consist of central caseation, epithelioid cells, and giant cells; and a surrounding lymphocytic wall. This structure is found most often in tuberculosis, but it may occur, exceptionally, in other so-called "chronic granulomas" such as syphilis, leprosy, sporotrichosis, etc., or even as the result of the deposit of nonliving substances in the tissues (tuberculin, trichophytin, oidiomycin, Frei "vaccine," etc.).

Tubercular means "characterized by tubercles."

Tuberculoid designates either: (a) structures not actually typical tubercles, but which resemble tubercles to a certain degree; or, (b) resembling the disease tuberculosis. In the former sense, it is strictly a morphologic and histopathologic concept; so, for example, the groups of epithelioid cells without caseation and with little or no lymphocytic reaction, as seen in sarcoids, are called "tuberculoid" structures.

Even with the closest possible adherence to the concepts and definitions outlined, the classification of the tuberculoderms is not simple, and, since we have not seen a concise tabular presentation in an American text, it would seem to serve a useful purpose to set forth a classification of the most important forms of skin tuberculosis as simply as possible.

In the table presented herein, which is derived from the classic tabulations of Lewandowsky,¹ Jadassohn³ and Martenstein and Noll,^{4b} no attempt is made to describe the various tuberculoderms or to elucidate many of the points of differen-

tial diagnosis. We have endeavored merely to bring out that this grouping of the various forms is based upon three main factors: (1) the immunologic status of the skin; (2) the resultant clinical and histological morphe and course; and (3) the immunologically determined bacteriologic findings. All statements, particularly those applying to the tuberculin test, express exclusively the *average* findings which become evident only through careful study of large series of cases. They do not apply to small groups, and still less to individual cases; nor do they take into consideration the many exceptions and the aberrant findings in a constant representative minority of cases. Biologic rules cannot be rigorously applied; they can be regarded only as indices of basic, wide, and important trends.

We believe that a study of the table, which indicates a possible correlation between tuberculin response, type of histologic reaction, and bacteriologic findings, must make it evident that the immunologic mechanisms, including hyperergy and hypoergy, are important determinants of the form and course of tuberculosis of the skin.

If this be true, it is logical to assume that, in a given case, factors producing alteration in the immunologic response of the skin to tuberculin might also exert a decided influence upon the existent tuberculoderm. In many instances, this assumption has actually been proved, and specific hyposensitization of the skin, by means of repeated intracutaneous injections of tuberculin in gradually ascending doses, has shown itself to be of decided therapeutic value.

We, ourselves, have achieved indubitable—sometimes even astonishing—results through the employment of this method in cases of hyperergic forms of skin tuberculosis, such as rosacea-like tuberculids, certain cases of tuberculosis papulonecrotica, tuberculosis indurativa, and in some cases of lupus vulgaris.

Undoubtedly it is not only of practical, but also of the very greatest theoretic interest that, by means of carefully graduated, repeated intracutaneous injections of ascending doses of

A SCHEMATIC CLASSIFICATION OF SOME OF THE IMPORTANT TUBERCULODERMIS **

Name.	Mode of infection	Clinical appearance, course and sequelae.	Histologic structure.	Demonstration of bacilli.	Tuberculin reaction as determined by quantitative intracutaneous testing (based on Moricant and Noll's and our own observations).
I PRIMARY TUBERCULODERMIS: A. <i>Tuberculous ulcers—very young infants</i>	Exogenous, heterogeneous, often after injury.	Rapidly growing ulcer sometimes with regional adenopathy. Often forelimb, then septicemia and death. Small, hard, indolent ulcer with regional nontender adenopathy. The ulcer may heal or may lead to lupus vulgaris or scrofuloderma or some other form. The regional glands may become calcified.	Bonal inflammatory reaction.	+++++	Usually negative. (Very few cases tested.)
B. <i>Tuberculous chancre—usually in young children.</i>	Exogenous, heterogeneous, often after injury.		First banal, later tuberculous.	++++	First negative, later ++++ or +++++ as in lupus vulgaris.
II SECONDARY TUBERCULODERMIS: A. <i>Hypertrophic forms with peripheral extension.</i> 1. Tuberculous lupus (lupus vulgaris, and as a subgroup, hematomatous lupus vulgaris)	Usually autogenous and external or by extension from mucous membranes. May be lymphogenous or hematogenous (postextrematic form—hematomatous lupus vulgaris).	Popular infiltrations, apple jelly nodules, peripheral extension, destructive scarring, chronic course. Often on face, but may occur at any site.	Tuberculous (usually no central caseation).	++ (with some difficulty—usually only by means of animal inoculations).	+++++ (strongly hypertrophic).
2. Tuberculous verrucous (anatomic tubercles, verrucous tubercles).	External in almost all cases. Autogenous or heterogeneous often after injury.	Usually on hand, extremity. Hyperkeratotic warty lesion, chronic course, little peripheral growth. Sometimes accompanied by lymphangitis and adenitis, leading with scarring.	Tuberculous structure mixed with banal inflammatory reaction (no caseation, but suppuration is sometimes present).	++	+++++ (strongly hypertrophic).
3. Tuberculous collagenosis (chilblains).	Lymphogenous or by direct extension from soft tissue, bones or lymph nodes.	Fluctuating "cold abscesses," sinus, etc. Usually spontaneous healing with scarring.	Tuberculous with a large amount of banal inflammatory reaction and suppuration.	++++	++++ (hypertrophic).

B. Hyperergic forms without peripheral extension (usually hematogenous and generally called tuberculids). ^{***}	Hematogenous.	Grouped follicular lichenoid papules. Spontaneous healing without scarring.	Tuberuloid (no caseation).	+ in very early lesions; difficult of demonstration particularly in fully developed lesions.	++++ (strongly hyperergic).
2. Rosacea-like tuberculid	Probably hematogenous.	Rosacea-like appearance: papules, sometimes pustules and erythema with some telangiectasia. Location: face, forehead, sometimes neck and chest. Chronic course. Little scarring.	Occasional tuberuloid structure. Otherwise similar to acne rosacea except for less suppuration and less strictly follicular or perifollicular.	Not accomplished.	+++ (strongly hyperergic).
3. Tuberculosis papulocroica (papulocroitic tuberculid, oculitis, follicles, etc.).	Hematogenous. Rare cases are lymphogenous.	Mainly on legs, arms and buttocks in young females, often with certain constitutional anomalies and with vascular dysfunction. Papules with round crusting or necrotic central ulcer. Depigmented scars with hyperpigmented margins. Spontaneous healing.	Tuberuloid, but with many areas of banal inflammation and necrosis. Superficial.	Very difficult but can be accomplished from the early lesion by numerous biopsies and guinea-pig inoculations.	Approaching energy: A relatively large number of cases show reduced sensitivity, while some are very strongly hyperergic.
4. Tuberculosis indurativa (erythema induratum of Batin).	Hematogenous.	Mainly on legs in young females of similar type as those with tuberculosis papulocroica. Large, soft, bluish lesions breaking down to ulcers. Spontaneous healing with scarring.	In the deep cuts and throughout the fat. Shows perivascularitis. Otherwise like tuberculosis papulocroica.	As in tuberculosis papulocroica.	As in tuberculosis papulocroica.

* We are greatly indebted to Dr. H. E. Moberg for his criticism and for helpful suggestions in the preparation of this table.

** This tabulation has been deliberately abbreviated to exclude many rarer forms, such as military ulcerative tuberculosis (often postexanthematous and due to a so-called "necrotic or nonspecific energy"), ulcerative tuberculosis of the face, such as the ulcerative tuberculosis of the face of J. Jadassohn, etc. The object throughout has been simplification and condensation, since we are endeavoring to present a simple and workable rule-of-thumb arrangement for the student, rather than an all-inclusive and absolutely correct, but thereby necessarily complicated and confusing tabulation.

*** We wish to emphasize again that the concept "tuberulid" is not to be juxtaposed to the concept "true tuberculosis." Tuberculids are forms of tuberculosis presenting certain distinguishing characteristics. Tuberculids are not necessarily devoid of living organisms, nor are typical tubercles necessarily lacking. While the concept "tuberulid" cannot be considered a strictly scientific one, it is nevertheless fairly well defined; it is of great value; and it seems essential that it be retained.

A SCHEMATIC CLASSIFICATION OF SOME OF THE IMPORTANT TUBERCULODERMS (Continued)

Name.	Mode of infection.	Clinical appearance, course and sequelae.	Histologic structure.	Demonstration of bacilli.	Tuberculin reaction as determined by quantitative intracutaneous testing (based on Martens and Nolte and our own observations).
C. <i>Relatively anergic forms (also considered as tuberculoid).***</i>					
1. Lupus miliaris disseminatus (faciei)	Hematogenous.	Bluish-red, pinhead- to large pea-sized nodules with typical central apple-jelly appearance, central necrosis, or apparent central pustulation. Usually confined to face, and often on eyelids. Chronic course. Heals with slight, often variciform scarring.	Fully developed tubercles.	Extremely difficult, but has been possible in some cases. ²²	Usually less sensitive than the normal; i. e., relatively anergic to tuberculin. But some cases are strongly hyperergic. This disease, in our opinion, forms the possible transition from tuberculous papulonecrosis and tuberculous indurative to the sarcoid forms below. [†]
2. Sarcoid forms.					
(a) Sarcoid of Boeck.	Probably hematogenous.	Superficial (Boeck) and deep (Darier-Haussy), bluish-red, torpid, benign nodules. Little or no tendency to break down. Scarring not severe, but sometimes atrophic scars result. Not infrequently part of generalized sarcoid disease (Boeck-Besnier's benign miliary lupoid), which includes alterations in the lungs (miliary sarcoid infiltration), spleen, liver, etc. There are also cystic changes in the bones, usually in the phalanges (osteitis tuberculosa multiplex cystoides of Jaccogli). Prognosis of these forms is good.	Tuberculoid, i. e., naked epithelioid cell tubercles with no central caseation and little or no peripheral lymphocytic zone, lying between connective tissue septa.	Almost always impossible; successful only in very early lesions or when transitions to other forms such as lupus vulgaris are taking place.	Usually much less sensitive than normals. This is the group with relatively excellent prognosis, and with so-called "post-tive, relative or specific tuberculin anergy" (in sharp contrast to the negative or nonspecific anergy found in miliary tuberculosis, postexanthematic ulcerative tuberculosis, and other forms, in all of which the prognosis is grave). [†] There is also said to be a high titer of tuberculin-neutralizing antibodies in the blood sera of these cases. ^{23, 24, 25}
(b) Sarcoid of Darier-Haussy.		(Here confined to deeper forms of true sarcoid structure otherwise identical with that of Boeck and not including the ulcerative forms which are probably closer to tuberculous indurative.)			
(c) Angiolupoid, lupus verrucosus and other rarer forms are here considered as belonging to this group.					

† All reactions of this sarcoid form can occasionally be produced by other agents, living or dead. Sarcoid reactions are found occasionally in many chronic infections such as leprosy, tinea, syphilis, etc., and after injections of various extracts such as tuberculin, trichophytin, etc.

old tuberculin Koch, the skin of patients originally reacting to dilutions of 1:1,000,000 and greater, can eventually be brought to tolerate relatively high concentrations with little reaction; and that, concomitant with this demonstrated reduced skin sensitivity to tuberculin, there is, not infrequently, a noteworthy improvement or a cure of the tuberculoderm; and that, later, there is, in some cases, a return of the *original tuberculin hypersensitivity* coinciding with a recurrence of the *original tuberculoderm*.

It would be most misleading to imply that the tuberculoderms, as a whole, religiously follow a schematic outline; or that their manifestations are based entirely and solely on the degree of skin hyperergy or hypoergy. On the contrary, there are many contraindications and mysteries which still await clarification, some of which may be due to the fact that the data assembled have been gathered through technics literally replete with possible factors of error.

For example, in our investigation, we are employing dead tuberculin, which surely contain only a few of the allergens and properties of the living bacilli; and, in general, we have been attempting to study immunologic processes, often of incredible fineness and delicacy, with clumsy and inadequate tools. Moreover, our tuberculin tests are being applied in the wrong place, *i. e.*, distant from the actual site in whose immunologic status we are interested; and are also being applied at the wrong time, *i. e.*, long after the actual time at which the immunologic status determined the character of the lesion.

In view of these and other facts, it is not the many contradictions that are astonishing, but rather the degree of order and regularity which can be demonstrated by even such crude measures. It is to be hoped that with improvement in methods, such as, for example, the antigen analysis (W. Jadasohn) fractionation and purification of tuberculins, dermatology will penetrate much farther than it has as yet into the nature of the immunologic processes which are obviously such important factors in tuberculosis of the skin.

CLINIC OF DR. A. HYMAN

FROM THE SURGICAL SERVICE OF DR. EDWIN BEER,
MT. SINAI HOSPITAL

THE DIAGNOSIS OF MALIGNANCY OF THE URINARY TRACT

THE importance of early diagnosis in malignant disease of the urinary tract cannot be overemphasized. A careful study of over 1500 cases of malignancy of the genito-urinary tract, makes one realize that much too often the disease is seen by the specialist in an advanced stage of development. A number of factors no doubt contribute to this unfortunate state of affairs. In the first place, too many patients first apply for treatment late in the course of the disease. At times the patient cannot be held responsible for this. Only recently I operated on a patient with a large kidney neoplasm in whom the initial hematuria occurred within a month of the time when she first sought medical aid. On the other hand, our records show that in over 60 per cent of cases of tumor of the kidney, more than six months had elapsed after the primary hematuria, before surgery was resorted to. The significance of hematuria is undoubtedly underestimated both by patient and physician. Unfortunately, in renal and vesical neoplasms, the hematuria is painless, at times lasting only a day or two, and ceases spontaneously not to reappear for months. Such a course of events often fails to impress the patient or his physician with the potentialities of the situation, and months of valuable time are lost waiting to see if another attack of hematuria supervenes. Since the early diagnosis of malignancy of the urinary tract rests to a large extent with the practitioner who is first consulted, he should realize that hematuria is a symptom only

too often associated with serious disease of the urinary tract. The physician should impress upon the patient the importance of a thorough urological examination, to determine the exact source and cause of the bleeding.

RENAL NEOPLASM

We have all been taught the textbook description of the three cardinal symptoms associated with renal neoplasm—pain, tumor and hematuria. Such a triad of symptoms generally denotes an advanced lesion, and under such circumstances the diagnosis presents no difficulties. Unfortunately, the symptomatology is at times so complex and protean in character, as to render the clinical picture most baffling. Not infrequently, there are few symptoms referable to the kidney and the first indication of a primary renal neoplasm may be the appearance of a metastatic lesion. We have found that the symptomatology of renal neoplasm may be classified under the following five types:

1. Hematuria.
2. Pain.
3. Tumor.
4. Gastro-intestinal and toxic manifestations.
5. Metastatic.

Hematuria is the outstanding symptom of renal neoplasm, and as an initial symptom was present in over 60 per cent of the cases, and during the course of the disease was present microscopically or macroscopically in over 90 per cent of the cases. Unfortunately, in some instances it is not always an early symptom. Occasionally it was noted only a few weeks prior to discovery of a large growth. The bleeding is painless in type, although the passage of clots down the ureter may produce colicky attacks of pain. Pain as an initial symptom may play an important rôle, as it often manifests itself before hematuria occurs. It was present initially in 30 per cent of the cases. The character of the pain may vary from a dull ache to sharp neuralgic pains down the back and thigh and is often described as lumbago or sciatica. Severe constant

neuralgic lumbar pains are often indicative of rupture of the growth through its capsule.

Tumor formation was present in almost 80 per cent of our cases, and its presence especially when associated with hematuria is of greater diagnostic value than other symptoms. Such a combination, however, generally denotes a lesion well advanced. Bimanual examination in the lateral position by displacing the kidney against the anterior abdominal wall, helps materially in detecting tumors otherwise not palpable. It is often impossible to differentiate a renal neoplasm from a splenic enlargement either by palpation, or by pyelographic studies.

Under the heading of general toxic manifestations, are certain symptoms such as loss of weight, cachexia and fever. These may be the first symptoms that point to a grave constitutional disturbance and in the absence of hematuria render the diagnosis very complex. As a rule, renal neoplasms do not produce the degree of cachexia so often seen in new growths of the intestinal tract. At times gastro-intestinal symptoms (anorexia, nausea and vomiting) dominate the picture giving the impression of a gastric neoplasm. These symptoms regarded as toxic manifestations due to absorption of the growth, often disappear immediately after nephrectomy. Fever is occasionally noted, probably due to a breaking down of the tumor, or infection. In over a dozen cases fever was noted without the presence of an associated pyuria. Israel, who first called attention to the fever associated with renal neoplasm, claimed the fever was not due to a necrosis of the growth, because the very large tumors in which we expect necrosis are not associated with fever, and in the tumors with necrosis fever was not noted. He considers it due to toxic products generated by the tumor and reports its incidence as approximately 20 per cent. The presence of fever may for a time obscure the clinical picture, cases of this type having been diagnosed as pyelitis or tuberculosis.

Metastases are common in renal neoplasm and every case of suspected renal tumor should be subjected to a careful ex-

amination clinically and by x-ray. These tumors metastasize through the blood stream and lymphatics. The frequency of pulmonary metastases should be borne in mind. Bony metastases are present in at least 15 per cent of the cases, emphasizing the value of radiographic examination of the long bones and skull.

The metastatic type is of considerable interest from the diagnostic point of view, especially in those cases where pain, hematuria and tumor are absent. We have had at least half a dozen such instances, in which metastatic lesions were the earliest evidence of disease, and the diagnosis of renal neoplasm was established only after a biopsy of the metastatic lesion led to careful study of the urinary tract. In one instance, a woman of fifty-five observed vaginal spotting for five weeks, then had noticed a swelling in the vagina for which she consulted her physician. Examination revealed a mass protruding from the vagina, of which a biopsy was made and reported hypernephroma. Attention was then naturally directed to the kidneys. There was no palpable tumor or pain, and careful examination of the urine revealed a few red blood cells. Cystoscopy and pyelography demonstrated a renal neoplasm. Nephrectomy was performed and the tumor proved to be a hypernephroma.

Varicocele as a symptom associated with renal neoplasm was first described many years ago, and is occasionally encountered. It differs from idiopathic varicocele in that it does not disappear on lying down.

Hypertension has not been found of special diagnostic import, although its association with renal neoplasm has in late years been stressed by numerous observers. Included in the clinical examination is a careful urinalysis. Occasionally, as in two of our cases, the diagnosis was established by finding tumor cells in the urine.

The most important aids in establishing the diagnosis of renal neoplasm are roentgenology combined with cystoscopy, retrograde pyelograms, and in recent years, intravenous urography. Cystoscopy and ureteral catheterization are of

considerable value, of course, in detecting the side involved. In over 90 per cent of the cases cystoscopy demonstrated either blood or impaired function of the diseased kidney. Manipulation of the ureteral catheter in the pelvis of the kidney so as to produce bleeding from the growth is of value when the patient is cystoscoped at a time when the urine is clear. Examination of the catheterized urine for tumor cells occasionally yields positive results.

Roentgenography is an invaluable diagnostic aid, and under this heading four methods are now available.

Simple roentgenography of the kidney frequently gives important information by determining the outline, size, form and position of the kidney. Unilateral increase in size or irregularity of the kidney should be regarded with suspicion. Calcifications in the tumor are occasionally noted and must be differentiated from stone and tuberculosis. The association of stone with renal neoplasm is rather infrequent, although we have noted it at least half a dozen times.

Pneumoroentgenography consists in the introduction of carbon dioxide into the perirenal tissues. We have had very little experience with this method in renal neoplasm but have found it of considerable value in outlining adrenal growths.

Urography of course is the most valuable diagnostic procedure at our disposal, and of the two methods—intravenous and retrograde pyelography, we have found the latter of much more value. In over 80 per cent of our cases there were definite pyelographic changes, indicative of neoplasm. In at least 10 to 15 per cent the interpretation of the pyelogram was exceedingly difficult, either the small size of the tumor produced insignificant pyelographic changes, or the deformities were not sufficiently characteristic to be differentiated from those caused by some of the lesions mentioned below. When in doubt, another pyelogram should be taken a few days later supplemented by intravenous urography. Occasionally, the intravenous dye is reflexly inhibited by the trauma of ureteral catheterization, and there is failure of visualization. It is therefore advisable

as a routine procedure to do intravenous urography before resorting to instrumentation.

Pyelograms of kidney tumors are so varied and bizarre in appearance that it would require too much time and space to describe the many changes encountered. There are any number of varieties of deformity and filling defects of the pelvis, calyces and ureter. In general, the characteristics of renal

Fig. 82.—Carcinoma of kidney. Tumor of upper pole—spreading of calyces

tumor are elongation or obliteration of one or more calyces, filling defects in the pelvis or calyces, displacement of the pelvis or upper ureter and inability of the pyelographic medium to enter the pelvis (Fig. 82). Extrarenal tumors may by pressure or displacement of the kidney produce pyelograms suggestive of renal neoplasm. We have at times encountered considerable difficulty in differentiating enlarged spleens and

retroperitoneal tumors from kidney tumors. A normal pyelogram does not necessarily exclude a neoplasm of the kidney. In three instances in which the tumor was confined to the lower pole of the kidney, without compromising either pelvis or calyces, the pyelograms were perfectly normal.

Intravenous urography has proved itself of considerable value, first by enabling one to obtain a bilateral pyelogram thus aiding in the differentiation between polycystic kidneys and renal neoplasms. It is of course of great help in patients who for some reason or other cannot be cystoscoped. This happened in one of our patients who had so profuse a hematuria that cystoscopy was unsuccessful in determining its source. In infants or children this method often renders cystoscopy unnecessary. The roentgenograms obtained are not as clear in detail as in retrograde pyelography, as good visualization depends on the amount of functioning kidney tissue. Nonvisualization, however, immediately focuses attention to the diseased side and taken in conjunction with other symptoms will often aid in establishing the diagnosis. The differentiation of abdominal masses either intra- or extra-urinary in origin, has been greatly facilitated by this method, so that its use should be a routine one. In general it may be stated that retrograde pyelography gives better detail, and is more reliable in the diagnosis of renal tumor. The main conditions to be considered in the differential diagnosis of renal neoplasm by pyelography are: extrarenal tumors, polycystic kidney, solitary cyst of the kidney, peri- or paranephritis, hydronephrosis, congenital anomalies especially fused kidneys, hypertrophied single kidneys, and filling defects due to uric acid calculus or blood clots in the pelvis of the kidney. Of all the conditions enumerated, blood clots in the pelvis, solitary cyst of the kidney, multilocular cysts not of the true polycystic type, and filling defects due to uric acid stones, give us the most trouble in the differential diagnosis. Colonic roentgenograms aid in determining the retroperitoneal position of the growth in relation to the colon.

The diagnosis of kidney tumors presents but little difficulty

when the classical triad of symptoms is present, or when hematuria and tumor are present. The cases presenting hematuria alone are often difficult to diagnosticate, especially if the functional tests of both kidneys are normal and pyelography is inconclusive. In elderly men where prostatic enlargement is complicated by hematuria, there may occasionally be difficulty in arriving at a diagnosis. One such instance was recently

Fig. 83.—Blood clots in pelvis, simulating tumor

seen. The patient, a man of sixty, complained of prostatic symptoms with the appearance of red blood cells in the urine. Flat films of the urinary tract were negative except for prostatic calculi. An observation cystoscopy showed an enlarged prostate and since the function of both kidneys as determined by indigo carmine was normal, the ureters were not catheterized. The red blood cells were thought to come from the enlarged congested prostate. A gross hematuria ensued a few

months later which led to more careful examination of the upper urinary tract by means of ureteral catheterization and pyelography. This demonstrated a tumor in the pelvis of the kidney. Occasionally, despite all our methods of instrumental and radiographic examination, one is left in doubt as to whether or not we are dealing with a renal neoplasm (Fig. 83). Under such circumstances exploratory operation is advisable.

TUMORS OF THE KIDNEY IN CHILDREN

Tumors of the kidney in children are practically all of the type known as the Wilms or mixed tumor. These tumors are supposed to take origin in embryonic tissue and are composed

Fig. 84.—Huge Wilms tumor in two-year-old child.

of collections of epithelium in the nature of tubular or glandular structures containing besides smooth and striped muscle fibers, cartilage, bone and proliferating tissue of mesothelial origin.

Clinically, these tumors in children manifest themselves by characteristics distinctly opposite from those seen in adults. The first symptom noticed in many cases is the presence of a large abdominal mass which may reach an enormous size, almost filling the entire peritoneal cavity and producing marked distention of the abdomen. Despite this large tumor, the child may look perfectly well, cachexia not appearing until some time later.

In a certain percentage of cases the disease first manifests itself by anemia, gastro-intestinal symptoms and loss of weight. Pain is not a predominant symptom and if present is not severe. As contrasted with tumors in adults, hematuria is of infrequent occurrence either as an initial symptom or at any stage of the disease. The diagnosis is not difficult. The same urological examinations practiced in adults can usually be carried out in children. Intravenous urography is especially of value, often rendering cystoscopy unnecessary (Fig. 84). Distant metastases are not as common as in tumors in adults, whereas involvement of the retroperitoneal glands occurs frequently.

NEOPLASMS OF THE BLADDER

For practical purposes we have found the following classification of bladder tumors meets most requirements. Although fibromata, angiomata, and other rare growths have been described, the great majority of cases presenting themselves for diagnosis belong to the epithelial group.

- (A) 1. Papillomata, benign.
2. Papillomatosis.
- (B) Papillary carcinoma.
 - (a) Superficial.
 - (b) Infiltrating.
- (C) Nonpapillary infiltrating carcinoma.
 - Adenocarcinoma.
 - Medullary carcinoma.
 - Squamous-cell carcinoma.

The most prominent symptom of bladder tumor is painless hematuria. The character of the bleeding varies according to the location of the growth, as for example, tumors at

the neck may only manifest themselves by terminal hematuria. The bleeding may be only microscopic, or total in character with the passage of clots. In certain cases an initial hematuria may disclose a large growth which evidently has existed for some time. Usually the benign growths produce no vesical irritation unless they are situated at the neck of the bladder. In malignant infiltrating tumors, infection of the urine generally takes place, resulting in dysuria and pain which may become very severe, rapidly undermining the patient's health. With increasing infection the urine becomes alkaline and incrustations form on the growth, adding to the patient's suffering. When the tumor is situated around the ureteral orifices, obstruction of the ureter may ensue, resulting in ureterohydronephrosis. Secondary infection of the kidney may further complicate the picture by causing symptoms of renal insufficiency. Distant metastases, especially osseous involvement, appear late in the course of the disease, although some observers have reported an incidence as high as 30 per cent. In a series of 16 cases of bladder carcinoma that had complete autopsy examinations, we found that 14 showed no evidence of metastases.

In all cases suspected of having a bladder tumor, a careful bimanual rectal or vaginal examination should be made for evidences of infiltration. Since the symptoms enumerated above may be caused by vesical conditions other than neoplasm, a routine urological examination is necessary in order to make a correct diagnosis. The most important diagnostic procedure is of course cystoscopy. The majority of tumors are situated on the base of the bladder, especially in the region of the ureteral orifices. It is usually possible to differentiate cystoscopically between the truly benign papillomata and carcinomata. Edema around the base of the growth and incrustations on the surface generally speak for malignancy. The relation of the tumor to the ureters should be carefully noted. Ureteral catheterization is indicated in every case where the growth is in close proximity to the orifice. At the same time by means of functional tests and pyelography an exact status

can be determined of the upper urinary tract. Biopsy specimens should always be obtained, our experience showing that there is no danger in spreading the disease by this procedure.

There are a number of cystoscopic pictures which may closely simulate bladder tumors. Intensive treatment of a benign papilloma by fulguration may cause a massive edema at the original site of the tumor, simulating an infiltrating malignant growth. A stone impacted at the ureteral orifice, or a

Fig. 85.—Carcinoma of bladder—tumor outlined by umbrathor and air inflation

tuberculosis of the kidney and ureter, may produce massive polypoid edema simulating a neoplasm. Sigmoid diverticulitis, carcinoma of adjacent organs, as rectum, uterus or ovary, may cause changes in the bladder mucosa suggestive of carcinoma of the bladder. Edema of the sphincter region caused by prostatitis, carcinoma of the prostate, and severe cases of cystitis cystica, bilharziasis, and syphilis are other lesions which may simulate a bladder tumor. Biopsy examinations will in

most instances serve to differentiate the various conditions mentioned.

Cystography is another important diagnostic aid. We use 6 per cent iodide supplemented by injections of air (Fig. 85). Such pictures will show changes in the bladder wall caused by infiltration, or the tumor itself may be seen projecting into the bladder. It will also serve to demonstrate tumors growing in a diverticulum by demonstrating a filling defect. Excretory urography is another valuable diagnostic aid, and in addition to the cystogram we obtain accurate information as to the condition of the upper urinary tract.

TUMORS OF THE URETER

Primary tumors of the ureter are relatively rare. We are mainly concerned with the epithelial growths, of which there are three varieties—papillomata, papillary carcinoma, and nonpapillary carcinoma. The true papilloma resembles the typical papillomata of the bladder and is generally multiple. The papillary carcinomata have a definite tendency to metastasize and involve regional and retroperitoneal lymph glands. These tumors are more often found in the lower segment of the ureter. The solid nonpapillary carcinomata account for almost 50 per cent of the primary ureteral neoplasms. Up to within a few years ago, 68 cases of primary carcinoma of the ureter have been reported in the literature. As an index of the relative occurrence of these tumors, we may cite our series of 209 cases of renal neoplasms recently reported; during the same period of time we observed 5 cases of ureteral carcinoma.

The symptomatology closely simulates that of renal neoplasm, pain, hematuria, and tumor constituting the triad of symptoms generally observed. Although hematuria may occasionally be absent, it is the outstanding symptom and occurs in at least 80 per cent of the cases. The hematuria differs in no wise from that of renal neoplasm. Pain is noted frequently either in the lumbar region dull in character or colicky, due to the passage of blood clots. If the growth invades adjacent structures the pain may simulate a severe sciatica or

lumbago. As a result of ureteral obstruction by the tumor, sooner or later there develops an ascending ureterohydronephrosis and the kidney becomes sufficiently enlarged to present a palpable tumor in the loin. Occasionally the growth may be palpated by vaginal or rectal examination. Small fronds of tumor tissue or atypical cells found in the urine may arouse suspicion as to the nature of the condition. The diagnosis can only be definitely established by careful cystoscopic and radiographic studies. An *x*-ray examination will generally rule out calculus. We must depend on cystoscopy, ureteral catheterization and urography to definitely establish the diagnosis. Occasionally, as happened in one of our cases, the tumor can be seen projecting from the ureteral orifice. A biopsy specimen was then removed confirming the diagnosis. The ureteral catheter generally encounters an obstruction. This obstruction followed by a copious flow of blood is characteristic of tumor. Obstructions in the ureter may be due to stone, tuberculosis or tumor. The absence of typical scratch marks on a wax bougie will rule out a calculus.

Retrograde urography by demonstrating an irregular filling defect gives valuable information. The filling defect produced by a uric acid calculus is generally more regular in shape, whereas that due to tumor has a moth-eaten appearance. Pyelography and intravenous urography will give us information as to the condition of the kidney and the ureter above the site of the obstructing neoplasm. Some of these cases show quite an advanced hydronephrosis, and many patients have been operated on for this condition, subsequently to be reoperated for the removal of the lower ureter with its tumor. Metastases are rather common, involving mainly the retroperitoneal nodes, liver and lung. Naturally all cases should have radiography of the chest before operative interference is considered.

CARCINOMA OF THE PROSTATE

Malignant disease of the prostate occurs in approximately 15 to 20 per cent of all patients with prostatic disease. The

local symptoms closely simulate those of benign prostatic obstruction. Gross hematuria is less typical of malignancy than of the benign type. Rather characteristic of malignancy are radiating pains in the back or thighs, often attributed to sciatica or lumbago. The diagnosis of malignancy rests on prostatic palpation. At least 80 to 90 per cent of prostatic cancers can be detected by rectal palpation. The characteristic signs are induration, fixation and nodulation. The gland may be large or small, only one nodule may be palpated or the entire gland may be riddled with nodules. Since osseous metastases are commonly seen, radiograms of the bones, especially the pelvis and spine should be routinely carried out. There are borderline cases of the chronic inflammatory type which closely simulate a malignant gland in its hardness. Prostatic calculi have been diagnosed as prostatic carcinoma; another reason for an x-ray examination to exclude this error. Cystoscopy, of course, should always be done. Distortions of the internal sphincter orifice, associated with edema are often deciding factors in establishing the diagnosis. When in doubt an aspiration biopsy of the gland through the perineum will often give us valuable information. In a recent case in which the diagnosis could not be definitely established by rectal palpation, cystoscopy disclosed a slight edema of the mucosa overlying the internal sphincter. By means of the resectoscope a few segments were resected from this region, and a definite diagnosis of carcinoma was made by histological examination.

MALIGNANT DISEASE OF THE TESTICLE

Every scrotal swelling should be carefully examined for the possibility of an underlying neoplasm. What appears to be a simple hydrocele may, after tapping, reveal an enlarged testicle which may prove to be a teratoma. Despite the fact that the testicle is an exposed organ easily palpated, the differential diagnosis of the underlying condition is not so simple. Teratomas at times develop so rapidly that when the patient is first examined metastases may already be present. The patient should be examined both in the erect and reclining positions.

Testicular tumors are generally unilateral, and occur more frequently in young people. The tumor is usually smooth and elastic although some neoplasms have areas cartilaginous in consistency. The growth is almost always limited to the testicle, the epididymis feeling normal. The testicle is usually insensitive, the overlying skin looks normal unless the growth is very large, then the skin has a glazed appearance. The spermatic cord is normal and generally sharply demarcated from the tumor. Often there is an inflammatory hydrocele which yields clear fluid on tapping. A bloody tap generally denotes invasion of the epididymis. On standing, the testicle has a feeling of weight to it. Inguinal or femoral lymph nodes are not involved until late in the course of the disease. Intra-abdominal and retroperitoneal metastases are rather common, so a careful abdominal examination should always be made. Roentgenograms of the chest should be taken routinely for the presence of metastases. Incision into the tumor for biopsy should never be undertaken, as the tumor is likely to spread rapidly and fungate following this procedure. Instead, an aspiration biopsy with a small needle is preferable. The use of the Aschheim-Zondek test as a diagnostic procedure should always be resorted to, although the limitations should always be borne in mind. Dean has recently summarized the results of this test as follows, "Assuming the patient appearing for examination with an enlarged testes of three months' duration, that he has received no treatment, and that there is no evidence of metastases.

"1. If the test is negative it is probable that he has no teratoma. It is possible that he has an adult teratoma which has not destroyed the interstitial cells of the testes.

"2. If the test shows 500 or less mouse units per liter of urine it is probable that the patient has a teratoma. This may be of an adult type, such as an adult cystic teratoma that has largely or wholly destroyed the interstitial cells of the testis, or it may be a smaller tumor of a low grade of malignancy which has not destroyed the interstitial cells. It is possible that the testis is the seat of syphilis, tuberculosis, interstitial

orchitis or any other condition that would cause swelling and complete destruction of the interstitial cells. It should be understood that it is exceptional for a testicle affected with syphilis, tuberculosis or interstitial orchitis to have all the function of the interstitial cells destroyed so that a positive test is obtained.

"3. If the test shows between 500 and 1000 mouse units per liter of urine, the tumor is probably a seminoma.

"4. An output of between 2000 and 10,000 mouse units per liter indicates an embryonal carcinoma with lymphoid stroma.

"5. An output of more than 10,000 mouse units per liter of urine indicates an embryonal adenocarcinoma or a chorio-epithelioma."

If a man has an untreated tumor of the testis and evidence of metastases, the Aschheim-Zondek test will be positive with probably more than 1000 mouse units per liter output.

As regards the differential diagnosis, the conditions simulating testicular neoplasm are tuberculosis, gumma, hematoma, and torsion of the spermatic cord.

CLINIC OF DR. MEREDITH F. CAMPBELL

FROM THE DEPARTMENTS OF UROLOGY AND DISEASES OF CHILDREN, NEW YORK UNIVERSITY COLLEGE OF MEDICINE AND BELLEVUE HOSPITAL

COMMON UROLOGIC CONDITIONS IN CHILDREN

ABOUT half of all children suffer some form of urologic disturbance before reaching puberty. In a large portion of these children, the disturbance is minor and frequently passes unrecognized. In the others the uropathy is of major importance and is sometimes fatal. In the majority of children with important urologic lesions, correct early interpretation of the presenting symptoms and a careful urinalysis will at once direct attention to the urinary tract.

A plea is herewith made for a careful examination of the urine in *any* sick child. Moreover, urinalysis should be performed in all children subjected to routine physical examination. In an astounding number of young patients in whom I have performed complete urologic examination, the discovery of an asymptomatic persistent pyuria occurred at the time of a routine urinalysis, when urologic disease was not even suspected.

Urologic conditions in children are here grouped according to the dominant symptom. It might be more fitting to entitle the communication Usual Causes of Common Urologic Symptoms in Infants and Children. Pyuria, disturbances of urination or nephritis are most commonly observed. The pyuric group are usually said to have either acute or chronic pyelitis. The clinical picture in the group showing disturbances of urination is usually called enuresis. Nonsuppurative nephritis

—Bright's disease—may be omitted from the present discussion. Other somewhat less frequent presenting manifestations are hematuria and pain or tumor along the urinary tract. These five symptoms constitute the principal indications for urologic examination in the young and the common lesions which may cause them are herewith briefly discussed.

PYURIA

Pyuria is the usual manifestation of urinary infection and always exists in the latter except during the first twenty-four hours of the disease in rare instances of hyperacute renal infection. Acute pyelonephritis, commonly designated as acute pyelitis, is usually correctly diagnosed, and with relatively simple therapeutic attentions generally runs a self-limited course. Although most of these patients are symptomatically cured within two weeks and the urinalysis is commonly negative after a month, in a large portion culture of the urine as late as six months after the acute illness, will show persistence of the etiologic organisms. In these cases of persistent bacteriuria, recurrences of acute renal infection are clinically recognized as recurrent acute pyelitis and are likely to appear with each acute focal infection elsewhere (tonsillitis, enteritis, etc.) or with the onset of acute urinary obstruction. In some children with acute renal infection a pyuria will persist after the patient becomes symptomatically well. If this pyuria resists intensive medical therapy for two to four weeks a complete urologic examination is indicated. In most of these cases a urinary anomaly which causes either obstruction or stasis will be found. In short, chronic pyuria and anomalous development of the urinary tract in children, are almost reciprocal.

Before subjecting the child to a complete urologic examination because of persistent pyuria, an *intensive course of medical treatment* is indicated. This includes urinary antisepsis which must be administered in much larger doses than customarily employed. My preference is methenamine (urotropin) and the basis of dosage is 10 to 12½ grains per day

per year of age. Thus a five-year-old child receives 50 to 65 grains in twenty-four hours. In children I have given twice this amount without untoward effect. As Helmholtz has shown, the therapeutic coefficient of methenamine is directly proportional to the urinary acidity. In methenamine therapy one should attempt to get the urine as near pH 5.5 as possible. At this titer methyl orange paper turns red and this indicator should be used rather than litmus paper. This acidulation can best be achieved by the use of ammonium chloride (which I prefer), ammonium nitrate or calcium chloride. These chemicals are available in enteric coated pills. The dose of acidulant usually equals that of the methenamine but must necessarily be altered to achieve or maintain the desired high acidity (pH 5.5). Recently I gave a young boy 200 grains of ammonium chloride before the desired acidity existed but once achieved, it was continued with less than half this dose. The medication is intensively given for four or five days when a rest period of a day or two is observed and during which time the urine is carefully examined, including culture. If infection remains the medication is resumed for another four days. As a rule, it is useless to persist with antiseptics longer than two weeks for if the urine cannot be sterilized in this time by this method, further similar efforts are likely to be futile. In infants the medication is given in the formula. With older children it may be given in solution with a palatable syrup. Hematuria induced by formaldehyde cystitis (urotropin reaction) is purely of vesical origin and will promptly disappear with withdrawal of the medication. Yet the vesical reaction is a favorable rather than unfavorable manifestation; it indicates an appreciable concentration of formaldehyde in the bladder urine.

Other urinary antiseptics include caprokol, pyridium, serenium, neutral acriflavine and methylene blue but if methenamine therapy is unsuccessful these other antiseptics are almost certain to fail.

The *kctogenic diet* is successful in sterilizing the urine of children in about 60 per cent of the cases. I have frequently

employed it following surgical treatment. It should be pointed out here, however, that the ketogenic diet will often sterilize the urine in patients with important anomalies of the urinary tract and for this reason a urologic examination is indicated in these patients even though, during the therapeutic period, the ketogenic diet was successful. In other words, the previous persistence of the urinary infection at once suggests the likelihood of a urinary anomaly and obstruction.

A correct anatomic diagnosis in chronic pyuria can be made only by a complete urologic examination. Residual urine may be present or the x-ray may demonstrate a urinary calculus. Although intravenous urography will often suffice to establish the diagnosis, in most instances it should be considered only a precystoscopic measure with which to elicit as much information as possible before the instrumentation is attempted. A complete urologic examination including cystoscopy, ureteral catheterization, divided renal function tests and retrograde pyelography can be performed without general anesthesia in about three fourths of all children. During the past four years in boys of three years and over I have used caudal anesthesia more than one hundred and fifty times. During the past year and a half I have used intravenous anesthesia (evipal) for brief instrumentation in more than 100 cases. It is fitting to note here that instrumental reactions following complete urologic examination in children are less than half as frequent and severe as in adults. Fear of an unfortuitous reaction need never be considered a contraindication to cystoscopic examination in a child.

Obstruction is the principal predisposing cause of urinary infection. The urinary tract above the obstruction becomes congested. The congested organ is more vulnerable to bacterial attack than the normal organ and organisms which are continually reaching the kidney by the blood stream find a suitable soil for growth. Not only does obstruction predispose to infection but once infection is established in the presence of obstruction the former can rarely be eliminated until the blockage is eradicated. Neuromuscular inertia such as is commonly

observed in cord bladder disease must also be considered as a cause of urinary stasis.

The common potential causes of urinary obstruction and by the same token the common predisposing causes of urinary infection are shown in Fig. 86. There may be a congenital stenosis of the preputial orifice or a stricture of a renal calyx. Between these anatomic extremes one or more of a legion of uro-obstructive conditions may exist. I have seen several boys said to have chronic pyelitis, but in whom the pyuria was proved to be perpetuated by a tight prepuce. Circumcision or a generous dorsal slit was commonly followed by a disappearance of the pyuria. This justifies the conclusion that the pyuria resulted from subpreputial urinary retention, stagnation and infection. Frequently the meatus is congenitally tight and produces urinary stasis. I have encountered this many times in boys and in a few girls, in some of whom the urinary back-pressure caused dilatation of the entire upper urinary tract. In a girl of thirteen months with congenital stricture of the anterior urethra, the cystographic bladder picture resembled that observed in advanced prostatic obstruction. Lesions commonly found in the deep male urethra are congenital valves, hypertrophy of the verumontanum, and congenital contracture of the vesical outlet. All of these may cause urinary obstruction with severe back-pressure; renal damage and important infection must eventually be anticipated. The majority of cases of these types that I have studied clinically were examined because of persistent pyuria.

Neuromuscular disease, usually designated as cord bladder, is not uncommon in children. There are 79 cases in my series. It is frequently associated with anomalies of lower spinal or neural development. Marked spina bifida occulta is frequently found in these cases. On the other hand, in some of the most advanced instances of cord bladder in children and with residual urine as much as 16 ounces, careful neurologic examination of the lumbosacral innervation failed to reveal alterations in either sensation or motor control. Occasionally in these

Fig. 86.—Direct and indirect causes of pyuria in children. 1, Stenosis of prepuce; 2, stenosis of meatus; 3, paraphimosis; 4, urethral stricture; 5, urethral stone; 6, urethral diverticulum; 7, periurethritis, periurethral abscess; 8, cowperitis; 9, congenital valves of posterior urethra; 10, hypertrophy of verumontanum; verumontanitis; 11, prostatitis; prostatic abscess; 12, contracted bladder neck; median bar; 13, periprostatis or abscess; 14, mucosal fold at bladder outlet; trigonal curtain; 15, stricture of ureteral meatus, ureteroceles; 16, ureterovesical junction stricture; 17, aberrant vessel; 18, congenital ureteral valves; 19, ureteral obstruction by diverticulum compression; 19', diverticulum, ureter opening into diverticulum; 20, ureteral stone; 21, ureteral stricture; 22, periureteritis; periureteral phlegmon or abscess; 23, ureteral kink; periureteral fibrous bands; 24, renal tumor; 25, ureteropelvic junction stricture; 26, aberrant vessel obstruction of upper ureter; 27, pelvic stone; 28, renal tuberculosis;

cases laminectomy is of value but generally the prognosis is unfavorable.

Bladder stone and diverticula are commonly associated with pyuria and are secondary complications in about 5 per cent of all cases of infravesical obstruction.

Congenital stricture of the ureter is the commonest obstructing lesion of the upper urinary tract. Except in the presence of infection congenital ureteral strictures rarely show sclerosis; they are merely anomalous narrowings comparable to similar narrowings frequently seen in the esophagus, at the pylorus, further down in the intestinal tract, and in the larger biliary ducts. Ureteral strictures occur most often at the lower end of the tube, are next most common at the upper end and are rarest in the middle. Frequently they are bilateral and may be multiple but I have never seen more than three strictures in one ureter. In 12,080 pediatric autopsies which I have recently tabulated, congenital ureteral stricture occurred in 72 instances (1:168). Yet it is an extremely common clinical finding in children with chronic pyuria (101 of 580 cases or 17.3 per cent). The demonstration of stricture requires a careful urologic examination. Many congenital strictures can be adequately treated by ureteral dilatation; for this purpose I have recently devised a special miniature dilating cystoscope (No. 17 F.) which will take a bougie as large as a slate pencil (No. 10 F.). This permits ample ureteral dilatation for any child up to the age of puberty.

It is axiomatic that an anomalous organ is more prone to disease than a normal one. Nowhere is this better exemplified than in ureteral reduplication, a condition found in about 0.5 per cent of all individuals. In 26,480 autopsies we found 136 cases reported, an incidence of 1:195. Yet in 580 children

29, stricture of caliceal outlet; 30, caliceal stone; 31, pyelonephritis; 32, pyonephrosis; 33, hydronephrosis; 34, perirenal suppuration; spinal disease (Potts', etc.), 35, hydroureter; 36, pericystic abscess rupturing into bladder; 37, seminal vesiculitis; 38, neuromuscular vesical disease; 38', cystitis; 39, urethritis; 40, folliculitis (Littre'); 40', folliculitis (Morgagni); 41, periurethritis; periurethral abscess; 42, endometritis; 43, cervicitis; 44, foreign body in vagina; 45, vaginitis; 46, skenitis; 47, folliculitis of introitus; 48, Bartholinitis; Bartholin abscess.

with persistent pyuria there were 58 cases (1:10) of ureteral reduplication, nearly twenty times the normal incidence. In all of these children the anomaly was a fundamental factor in causing the pyuria to persist. In many of these cases both divisions of the ureter and of the reduplicated kidney were involved by infection or obstruction. Yet in a surprising number only half of the reduplicated organ was diseased and in 13 children ranging in age from five months to eight years ureteroheminephrectomy (removal of the diseased half of the kidney and the reduplicated ureteral segment draining it) cured the pyuria.

In some instances the ureteral orifice is ectopic and opens in the urethra or, rarely, in the vestibule. A ureter with an ectopic orifice almost always shows evidence of urinary stasis, and infection is an extremely common complication. In a girl of thirteen months with persistent pyuria since the age of five months urologic examination revealed complete bilateral ureteral reduplication. The ureter from the lower pelvis of the kidney on each side opened normally in the bladder. The ureter from the right upper pelvis—and this was uninfected—opened in the posterior urethra. The ureter from the pyonephrotic upper segment of the left kidney opened in the vestibule. By squeezing the left loin thick pus resembling toothpaste was seen to exude from the ectopic opening in the vestibule. Ureteroheminephrectomy cured.

Ureteral calculi are occasionally found. In a girl of nineteen months examined because of chronic pyuria, a small uric-acid stone was seen in the bladder and two uric-acid stones were demonstrated by negative pyelography and scratch of a wax bulb in the left ureter, on which side the pyuria originated. Spontaneous passage of these stones followed instrumental dilatation of the ureter.

Aberrant vessels are frequent causes of ureteral obstruction. About a fourth of all kidneys show anomalous vessels which pass from the upper pole or from the lower pole, chiefly to the vena cava or aorta. Those vessels which pass from the lower pole cross, and frequently cause pressure on the upper

ureter. This induces hydronephrosis which often becomes infected and pyuria persists. Quite uniformly these children are said to have chronic pyelitis. I have now operated on 17 cases of vascular obstruction of the ureter in children. In three of these, antecedent attacks of Dietl's crises induced by the vascular obstruction had caused the appendix to be removed. When renal injury is not marked, resection of the vessels is frequently curative. Most children, however, are not seen until the hydronephrotic damage is extreme and nephrectomy is required.

Rarely, an anomalous vascularization in the depths of the female pelvis may cause ureteral obstruction. The uterine artery is usually the obstructing vessel but a branch of the iliac or hypogastric vessels may cause the pressure. In a child of thirteen months with persistent pyuria the diagnosis of vascular obstruction of the lower ureter was made by urography and was confirmed at operation. An artery, vein and band of fibrous tissue firmly compressed the ureter at a point 1 cm. above the ureterovesical junction and was indicated in the urogram as a transverse filling defect. I have seen apparently this same condition in three other young children but in whom the diagnosis lacks surgical confirmation.

Stones in the kidney are not uncommon in children; there are 10 cases in my personal series. I have removed a kidney for stone pyonephrosis from a boy of six months and from a girl of two years. Doubtless most of the small renal stones of childhood pass spontaneously; the painful syndrome accompanying their passage is usually interpreted as intestinal colic. Many calculi in childhood are composed of pure uric acid and hence are not radiopaque. They must be demonstrated either as (1) negative or vacuolated shadows in the radiographic media or (2) by passage of a wax-bulb ureteral bougie which the stone scratches. Sometimes renal stones in children can be removed by simple pyelotomy.

Chronic suppurative pyelonephritis is occasionally found. In some of these cases neither antecedent obstruction nor any other predisposing factor can be demonstrated at the time the

examination is made. Moreover, identification of these etiological factors is frequently obscured by marked secondary inflammatory changes in the ureters and renal pelves.

Chronic renal tuberculosis must not be overlooked. One in every 50 cases of so-called "chronic pyelitis" in children is surgical renal tuberculosis. The dominant clinical manifestations almost always lead to the diagnosis cystitis—acute or subacute. Having established the diagnosis nephrectomy, when not contraindicated by bilateral renal involvement or by functional insufficiency of the "better" kidney, offers the only hope of cure. There are 18 cases in my series.

DISTURBANCES OF URINATION

Dysuria or difficulty in urination is most often due to congenital obstruction in the prostatic urethra but vesicospincterospasm caused by inflammation may produce this symptom in both males and females. Moreover, I have seen several cases of extreme dysuria in young boys with a congenitally tight meatus; in many of these cases secondary ulceration—the ulcerated meatus—occurred. Meatotomy cures the meatal obstruction; transurethral resection of the deep congenital urethral obstructing lesions is the usual indicated treatment.

Enuresis is the commonest disturbance of urination in children and doubtless in 95 per cent of the cases is purely a functional disorder. We strongly believe, however, that urologic examination is indicated in those enuretic children uncured in two to three months by medical, physical or psychologic therapy. In a personal series of 532 children thus subjected to cystoscopic examination, uropathy adequate to explain the clinical picture was found in 60 per cent. Fifteen per cent of the latter children had residual urine, that is, they could not empty their bladders. In females with enuresis urethrotigonitis is the commonest lesion found. In enuretic males congenital obstructive lesions at the bladder neck or in the posterior urethra are of high incidence. In children of all ages inflammation due to unsuspected urinary infection is often the fundamental etiology of the enuresis and in 3 instances

in my series nephrectomy for renal tuberculosis was the essential treatment. Although one wishes to believe that well-trained pediatricians would not fail to recognize enuretic manifestations due to a tight prepuce or meatus, bladder stone, chronic pyelonephritis or renal tuberculosis, for example, my

Fig. 87.—Usual sources of hematuria.

experience has shown that this unusual conception of the potential etiology of so-called "enuresis" is not generally held.

When no urologic basis for the enuresis is found psychotherapy may be continued with the assurance that no important disease is progressing in the urinary tract. When a urologic

lesion is demonstrated, the treatment is based entirely on pathology. In a great many girls with urethrotrigonitis, ample dilatation of the urethra and the local use of dilute silver nitrate is curative—the identical treatment commonly employed in urethrotrigonitis in adult women.

HEMATURIA

Hematuria in a child usually means nephritis, renal tumor, or renal tuberculosis. Yet in several boys with moderately profuse hematuria the bleeding came from an ulcerated meatus. Except when due to acute glomerular nephritis hematuria always indicates a thorough examination. Occasionally the bleeding results from renal congestion coincident to an obstructive lesion. The commonest causes of hematuria are shown in Fig. 87.

PAIN

Pain is seldom the only symptom of urologic disease in children. The most striking instance I have observed occurred in a five-year-old girl with a congenital ureteral kink. Her only complaint was pain in the left renal region; urinalysis was thoroughly normal. Urologic examination revealed a fixed kink at the junction of the middle and upper third of the left ureter and with the mobilization of the kink and high fixation of the kidney, the pain disappeared. Periodic ureteral dilatation now insures free drainage.

TUMOR

Embryonal adenomyosarcoma of the kidney is the commonest abdominal tumor of children, and of all tumors in children is outranked only by those of the orbit. These renal tumors (Wilms) are commonest before the age of five years; are seldom correctly recognized until the growth is far advanced, and to date the mortality has been about 95 per cent. Of 52 cases, only 2 lived five years. I have 3 cases which appear to be cured more than one year postoperative. One of these is a girl from whom an embryonal adenosarcoma weighing 500 Gm. was removed at the age of six weeks; she shows

no evidence of recurrence one and one-half years later. In cases of this highly malignant tumor recurrences are usually noted within six months and patients who show no recurrence within a year will probably remain cured. Nephrectomy offers the only hope of cure and the combined use of irradiation therapy and nephrectomy offers the only prospect for reduction of the present mortality. Preoperative irradiation totaling 3000 to 5000 r. should be given in divided daily doses over a period of about three weeks (Coutard technic). As a result of this irradiation many of these renal tumors will become no longer palpable. Three to four weeks following the irradiation the kidney should be removed. A month postoperative a course of irradiation similar to the preoperative therapy should be given. Because metastasis is frequent, the irradiation should include the abdomen and chest although not so intensively as the primary tumor.

Neuroblastoma of the adrenal simulates and is usually erroneously diagnosed renal tumor. It occurs half as often as renal tumors. Most retroperitoneal "lymphosarcomas" in children are adrenal neuroblastomas. The tumor seldom invades the kidney, it metastasizes widely, and is almost always fatal.

Fortunately not all palpable tumors of the renal region are malignant. *Hydronephrosis* is the commonest palpable renal tumor in children and most commonly results from: (1) congenital stricture at the ureteropelvic junction or (2) vascular obstruction by anomalous lower polar vessels which compress the ureter at or near its union with the pelvis. Preoperatively, the likely etiology of the hydronephrosis can usually be deduced by excretory urography. This diagnostic aid, however, is of no value when the renal function is extremely low; retrograde urography must be employed. In some of these cases conservative surgical treatment, *c. g.*, resection of obstructing vessels or a ureteropelvioplasty will relieve the obstruction. Yet in most children extreme renal damage demands nephrectomy.

Undescended testicle is the commonest disturbing condition

of the spermatic tract in boys. Boys with undescended testicle should be given the benefit of hormone therapy (antuitrin-S; follutein). If this fails, the testicle should be brought down into the scrotum, preferably by the Torek procedure and preferably by the eighth year. In cryptorchid patients with a complicating hernia, only surgical treatment merits consideration. It should be noted that in some patients in whom the use of glandular extracts is apparently followed by descent of the testicle, the gland recedes to its former position when the hormone therapy is discontinued.

SUMMARY

Attention has been directed to the more common lesions which help to cause chronic pyuria in children. The high incidence of these conditions and the relative infrequency of their correct recognition, especially when the upper urinary tract is involved, is a challenge to pediatricians and urologists alike. In chronic pyuria a congenital anomaly of the urinary tract should be assumed to exist until proved otherwise.

Although enuresis is almost always a functional condition urologic examination of the treatment-resistant cases shows demonstrable pathology in nearly two thirds.

Infants and children tolerate complete urologic examination better than their elders; reactions are only half as frequent and are much less severe in the young patients. Certainly fear of undesirable sequelae should never be permitted to rule against a thorough urologic investigation when it is otherwise indicated.

One admonition more than any other I would give: examine the urine.

SYMPOSIUM ON RELIEF OF PAIN

IN a recent number of the Medical Clinics there was a Symposium on Pain. In this issue we have carried the thought a little further and have gathered a group of clinics on the Relief of Pain. It has been our endeavor to cover the regions of the body in which the relief of pain is the problem of the general practitioner.

The following clinics are included in this Symposium:

Abraham Ettleson: RELIEF OF HEADACHES, FACIAL NEURALGIA, GLOSSOPHARYNGEAL NEURALGIA, SUPERIOR LARYNGEAL NEURALGIA, OCCIPITAL NEURALGIA, PAIN FROM SLUDER'S NEURALGIA.

Robert O. Ritter: RELIEF OF LUMBAGO AND SCIATICA.

Louis T. Curry: TREATMENT OF EARACHE.

Charles W. Freeman: PAIN IN THE DENTAL FIELD.

Walter R. Fischer: RELIEF FOR PAINFUL FEET.

G. K. Fenn: PAIN SIMULATING THAT PRODUCED BY CORONARY DISEASE.

N. C. Gilbert: TREATMENT OF ANGINA PECTORIS.

Lowell D. Snorf: PAIN IN THE ABDOMEN: CLINICAL SIGNIFICANCE AND CONSIDERATION OF RELIEF.

J. P. Greenhill: RELIEF OF PAIN ARISING IN THE FEMALE PELVIS.

CLINIC OF DR. ABRAHAM ETTLESON

LOYOLA UNIVERSITY

RELIEF OF HEADACHES, FACIAL NEURALGIA, GLOSSO-PHARYNGEAL NEURALGIA, SUPERIOR LARYNGEAL NEURALGIA, OCCIPITAL NEURALGIA, PAIN FROM SLUDER'S NEURALGIA

RELIEF OF HEADACHES

THE clinic today concerns itself mainly with the relief of headache due to migraine. It is to be understood that the following outline of treatment is intended only for those patients in whom a diagnosis of migraine is made after all other causes of headache have been excluded. For a general discussion of migraine the reader is referred to the literature on that subject.

In order to obtain relief from this distressing affliction, it is necessary to avoid possible precipitating or exciting causes of attacks of migraine such as fatigue, mental or physical, continued worries, fears and excitement, indiscretions of eating, drinking or smoking, and exposure. In a positive direction, the sufferers from migraine should adhere to a regular hygiene of living with regulation of diet and bowels, abundance of fresh air, sleep, and light daily exercise. On general medical principles physical defects should be corrected, although their correction may not bring relief from the headaches. Likewise the removal of foci of infection and the cure of constipation may fail to produce the desired results.

With recent advances in allergic and endocrine disorders, treatment for the relief of migraine has been undertaken by specialists in these fields with reported variable success.

Among the allergic disorders food disagreements have been blamed for the periodic headaches, for which skin tests are made, and "elimination diets" are given, or protein desensitization with peptone or other nonspecific protein is done. In the endocrine field various drugs from the selection of organotherapy are employed, particularly theelin one ampule every other day for one week before regular menstrual periods, and placental hormone (emmenin), an emmenagogue, or gynergen before menstruation. The rationale for the use of these drugs is the frequent association of attacks of migraine with the menstrual period. It is wise not to promise the sufferer relief from these measures, for failures from these forms of treatment are common; and promise unfulfilled, confidence is lost.

Regarding the use of drugs for the relief of migraine many have been tried, but none is specific for the disease. Among them the two which have received the most credit for affording relief are fluid extract of *Cannabis indica* in the largest dosage tolerated, starting with 2 minims every four hours, and sodium thiosulphate 15 grains intravenously. The former probably produces its desirable effects by depressing the sensory pathways in the spinal cord, and, in large doses, producing sleep. The favorable influence of thiosulphate on headache is not understood. The bromides, luminal, calcium salts, salicylates, and caffeine have been tried, each alone or in combination, with varying results, but on the whole they have not been successful. Morphine is to be avoided, or used only as a last resort, because of the danger of addiction.

Ligation of the middle meningeal artery on one or both sides is being done today after all palliative measures have been tried and failed. In the few reported operated cases and in those known to me, the ligation effected relief from the severe headaches. The operation, which is only slightly more than a subtemporal decompression, can be done under local anesthesia in the upright position. It is a relatively simple and short procedure, practically entirely devoid of risk.

The reason for the success of this procedure is explained by the theory that migraine headaches are caused by vaso-

motor spasm of cerebral and meningeal vessels brought on by an irritative affection of the cervical sympathetic ganglia. This supposition is rendered plausible by the recent demonstration of nerve fibers in cerebral vessels. Spasms of the latter produce the various visual disturbances, aphasia, paresthesias, and psychic phenomena of migraine, while constriction of the meningeal vessels is thought to be the cause of the severe hemicrania through the involvement of the sympathetic plexus encircling the latter. Hence, severing the artery destroys the sympathetic plexus around it, thus preventing spasm of the vessel. On the other hand, avulsion of the sensory root of the gasserian ganglion on the affected side has not brought relief from migraine headaches.

For the relief of an attack "nearly every patient has his own pet remedy" (P. Bassoe). A hot mustard foot bath, or a warm full bath, followed by rest in bed in a quiet, darkened room with warm compresses to the head and eyes may afford relief from the intense headache. One or more of the coal tar products—phenacetin, aspirin, pyramidon, each in 5 grain doses, and inhalation of the contents of a pearl of amyl nitrite may be effective.

RELIEF OF FACIAL NEURALGIA

We shall consider here chiefly the relief of trigeminal, or, as commonly called, trifacial neuralgia. All other causes of pain in the face must be looked for and excluded before diagnosis of tic douloureux is made. In this regard it is particularly important to distinguish between psychalgia and true paroxysms of trigeminal neuralgia. In the latter condition the pain always occurs in paroxysms and is limited to the true anatomical distribution of the fifth nerve on one side, never spreading across the midline or beyond the nerve area, while in the former the pain may be continuous and located anywhere in the face, head and neck, or shoulders.

Having determined that the pain in the face is due to major tic, relief may be obtained by one of several procedures. Since one of the cardinal features of trifacial neuralgia is the presence of hyperesthetic areas or trigger zones on the face,

scalp, or in the mouth which when touched set off a paroxysm, the sufferer will have learned from painful experience to leave these tender points absolutely untouched. He will therefore refrain from rubbing his eyes, touching, washing and wiping his face or lips, combing his hair, brushing his teeth, laughing, talking, blowing his nose, sneezing, coughing, or moving his jaw, according to the branch of the fifth nerve affected. He will also have learned to avoid cold drafts and chill, excitement and noises.

As in migraine, here also on general medical principles all possible local causes of pain in the face, as infected teeth or nasal sinuses, should be treated, although no relief may follow. By the time the patient will have drifted into the hands of a neurologist or neurosurgeon, the victim already will have sacrificed most or all of his sound teeth and submitted to one or more operations on his nose and sinuses without avail.

For temporary relief of pain deep inhalation of 20 to 30 drops of trichlorethylene (chlorylen) poured on a piece of gauze while patient reclines on one side is recommended. This drug acts selectively on the fifth nerve. All other drugs including morphine are worthless in the treatment of this affliction.

Roentgen radiation over the gasserian ganglion has lately been tried, but the fact that it has not displaced other measures after several years of trial indicates the limited efficacy of this procedure. However, postherpetic neuralgic pain is relieved by this method but not by operation.

Alcohol injection into the nerve trunks was the best known method of treatment until surgery began to be employed for the relief of facial pain. This method is still useful in many cases, especially in those in whom surgery is contraindicated. It is for the benefit of these cases that the technic of alcohol injection is here given in detail. Alcohol injection offers only temporary relief, the pain recurring in from six months to a few years. It is always advisable to inform the patient about the numbness of the face that follows injection.

The *modus operandi* of alcohol when injected into a nerve

explains the reason for only temporary relief from pain. Alcohol when injected into the nerve causes destruction by coagulation of the nerve fibers at the site of injection followed by degeneration of the nerve elements *below* this point to the periphery. The injection, which is excessively painful over the area supplied by the nerve, produces anesthesia almost immediately. So long as the nerve fiber *above* the point of injection and its nerve cell of origin within the ganglion are intact, a new nerve fiber will commence to grow downward from the cell body during the process of nerve regeneration, and by this means the damaged nerve is renewed and its conduction powers are re-established after an interval varying from six months to two years. Injection of the gasserian ganglion may offer permanent relief, but it is fraught with great danger except in the hands of a highly skilled operator. The alcohol might enter the optic nerve and produce blindness, or the oculomotor nerves and cause paralysis, or the cavernous sinus resulting in thrombosis. It makes later resection of the sensory root much more difficult. It may lead to corneal ulceration just as resection of the sensory root, and hence has no advantage over the latter procedure. In short, injection of the gasserian ganglion is not recommended.

Furthermore, an excellent knowledge of the anatomy of the trigeminal nerve is necessary to be successful with alcohol injection for the relief of tic douloureux. The depth to which the needle must be inserted in the tissues is very important, and can be determined by placing a small piece of rubber on the needle (Fig. 115) before insertion to the estimated depth of the nerve to be injected. The surest sign that the needle is in the correct position is the occurrence of pain in the area supplied by that nerve. The point of the needle must puncture the nerve trunk so that the alcohol actually penetrates among the nerve fibers.

The needles used are of stainless steel and flexible, like the kind employed in local infiltration anesthesia. The skin at the site of injection is made antiseptic in the usual manner. The alcohol is *never* injected into the nerve until anesthesia

has resulted from injecting a few drops of 2 per cent novocain. The syringe with novocain is then replaced by one with 95 per cent alcohol and the nerve is injected with it one drop at a time until the area of the nerve is totally anesthetic to pain, and there is no longer felt a burning sensation in the cutaneous distribution of the nerve.

Neuralgia of the First Division.—*Technic for Injection of the Supra-orbital Nerve.*—(Figs. 111, 112.) The supra-

Fig. 111.—Points of injecting the supra-orbital and infra-orbital nerves.

orbital notch is marked by the index fingernail of the left hand pressed upon it while a small flexible needle is slipped along the fingernail down into the notch, just below the eyebrow, at a distance of about 1 inch from the middle. As the point of the needle hits the bone, the patient will experience a sharp pain up to the top of the head. This is the sign that the needle is in the correct position. Now 2 or 3 drops of 2 per cent novocain solution are injected, and the sensation

of the forehead is tested by a pinpoint. If anesthesia in this area has resulted, the syringe with novocain is replaced by one with 95 per cent alcohol and about 10 drops are injected slowly, 1 drop at a time. There should result anesthesia of the forehead and top of the head up to the midline, except

Fig. 112.—Points of injection of supra-orbital, infra-orbital, maxillary and mandibular nerves. 1, Supra-orbital notch; 2, infra-orbital foramen; 3, coronoid process of mandible; 4, notch of mandible.

the central triangle of the skin between the eyebrow and midline which is spared, because it is supplied by the supra-trochlear nerve.

Neuralgia of the Second Division.—(a) *Technic of Injection of the Infra-orbital Nerve.*—(Figs. 113, 111, 112.)

The infra-orbital foramen lies about 1 inch from the midline. A long needle is inserted at a point about one-fourth of an inch outside and above the angle of the ala nasi, the insertion being made down to the bone in an upward and slightly outward direction. It is important to keep the left forefinger firmly pressed against the rim of the lower margin of the orbit, to insure that the needle does not slip over the orbital margin and so penetrate the orbit, where serious damage might be done. The patient will complain of pain in the nose and

Fig. 113.—Anatomical view showing injection of infra-orbital nerve.

upper lip as soon as the needle strikes the nerve. Three or 4 drops of 2 per cent novocain solution are then injected, which will be followed by anesthesia of the upper lip, lower eyelid, cheek, and side of nose. Then 1 cc. of 95 per cent alcohol is slowly injected, a dressing being held firmly pressed against the cheek close to the needle to prevent swelling.

(b) *Technic of Injection of Second Division at Foramen Rotundum.*—(Figs. 114, 115, 112.) Injection of the second and third divisions at the foramen rotundum and foramen

ovale, respectively, and gasserian ganglion should be attempted only by the skilled physician. A skull with mandible in place always should be before the operator for guidance by landmarks during injection of the second or third division. For injection of the second division it is well beforehand to mark off on the needle $4\frac{1}{2}$ to 5 cm. from the point upward. The method of approach to the foramen rotundum and foramen ovale is through the outside of the cheek.

Fig. 114.—Lateral view of skull showing anatomical landmarks for injecting the second and third divisions.

First feel the coronoid process of the mandible, then insert a long, flexible needle behind this process. Now direct the needle slightly forward at an angle of from 15 to 30 degrees, and upward at an angle of about 15 degrees.

The object is to hit the external pterygoid plate (Fig. 116), and then to manipulate the needle forward until its point is felt to slip in front of the anterior edge of the plate, where the nerve will be found at a slightly greater depth. If the nerve is not found on the first attempt the needle must be

partially withdrawn and its angle of direction altered slightly upward or downward, until the nerve is found. At a depth of 5 cm. the needle should be in the foramen rotundum. The penetration of the nerve by the needle will be indicated by pain in the distribution of the second division in the upper jaw, teeth and gums. The injection first by novocain and then by alcohol is made as for the third division injection. (See below.)

Fig. 115.—Anatomical view showing the foramen rotundum and foramen ovale at sites for injection of the second and third divisions respectively. Piece of rubber marks the length of needle to be inserted down to the nerve.

Neuralgia of the Third Division.—(a) Peripheral injection of this division is made in the mental foramen, through the cheek or into the inferior dental nerve on the inner side of the ramus of the lower jaw. (Figs. 116, 117.)

(b) *Injection of Third Division at Foramen Ovale.*—(Figs. 114, 116, 115, 112.) A long flexible needle is inserted in the middle of the zygomatic arch, through the sigmoid notch of the mandible, about 1 inch forward from the middle of the

external auditory meatus. Push the needle inward pointing it slightly upward and backward. Pain referred to the ear indicates that the eustachian tube has been touched because the needle is too far backward. Withdraw it a little and push it further forward. Pain felt in the throat and back of the tongue means that the needle has been pushed too far. By the method of trial and error the third division can even-

Fig. 116.—Anatomy of trigeminal nerve. 1, External pterygoid process of sphenoid bone; 2, mental foramen; 3, ophthalmic division; 4, maxillary division; 5, mandibular division; 6, gasserian ganglion; 7, sensory root of gasserian ganglion.

tually be found. As soon as the needle strikes the nerve, the patient complains of pain in the lower lip, chin, or tongue. Inject 2 or 3 drops of 2 per cent novocain and test these parts for anesthesia. When this appears change the syringe to 95 per cent alcohol and inject slowly a drop at a time. As the alcohol is injected, a burning sensation is felt in the lower lip, cheek and chin, and a wooden feeling spreads along the

lower jaw and in front of the ear. The burning sensation soon passes off whereupon more alcohol is injected, 2 or 3 drops at a time, until the anesthesia is complete and no more burning is experienced. The pain then ceases at once.

If the burning pain spreads to the nose, cheek, and eye, and anesthesia appears over the upper two divisions of the nerve, this indicates that the gasserian ganglion has also been injected.

Successful injection results in anesthesia to pain and touch on the side of the lower lip, inside of cheek, lower jaw, teeth, gums, and tongue, on a strip of skin extending from the lower

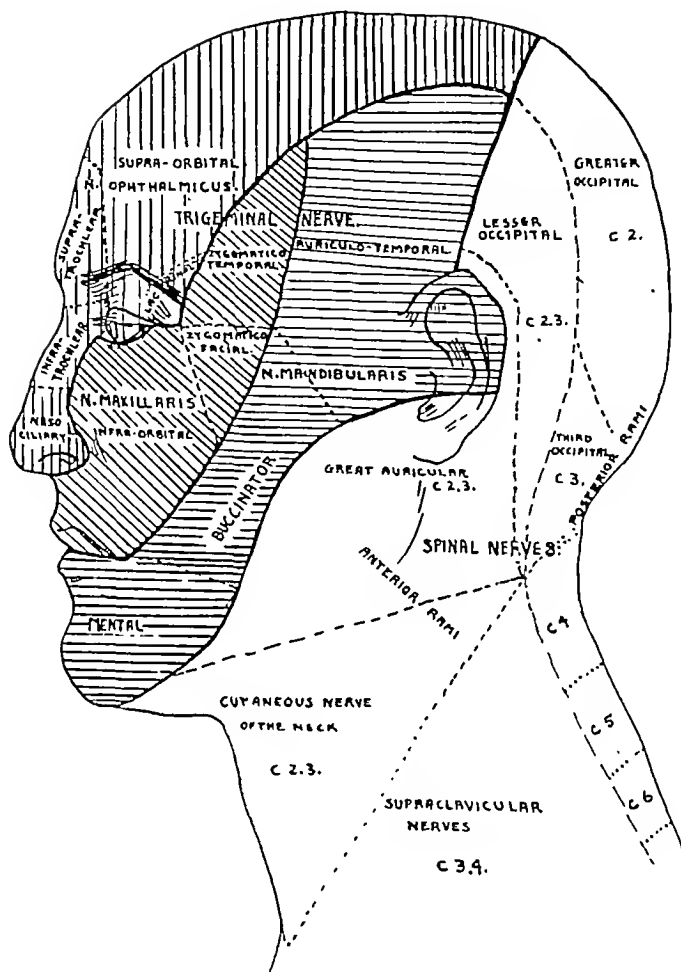

Fig. 117.—Mandible showing mental foramen.

angle of the mouth toward the temple, and in the external auditory meatus and tympanum (Fig. 118). There will also be paralysis of the masseter, temporal and pterygoid muscles, so that the lower jaw when opened widely will be pushed toward the side injected.

Following an injection the patient may complain of deafness and intense vertigo and he may vomit and have facial paralysis and coarse nystagmus due to leakage of the alcohol toward the cerebellopontine angle. This can be prevented by making the injection very slowly.

The chief danger, arising from the unintentional injection of the gasserian ganglion, is corneal ulceration. This can be

 ▨ MAXILLARY DIVISION.
 ▩ MANDIBULAR DIVISION.

FIG. 118.—Sensory area of head showing the three divisions of the fifth nerve.

recognized early by the steamy ground-glass appearance of the cornea, with circumcorneal injection. If this is observed, a drop or two of atropine in the eye with closure of the lids

by a firm bandage for twenty-four hours may prevent further ulceration. Whenever the corneal reflex is abolished after an injection of the foramen ovale, the eye requires special attention, by shielding it with an eye shield or crystal and irrigating with 2 per cent boric acid lotions and instillation of 10 per cent argyrol.

Avulsion of the sensory root of the gasserian ganglion, also referred to as subtotal resection of the root, or retrogasserian neurectomy, offers the only permanent relief from trigeminal neuralgia. In this operation the sensory root fibers (Fig. 116) of the second and third divisions are destroyed never to regenerate functionally. The ophthalmic division and the motor root of the fifth nerve are left intact whenever possible to avoid the risk of keratitis and paralysis of the jaw. Nearly the entire operation can be done under local anesthesia in the sitting position, via the subtemporal route. Sufferers from trifacial neuralgia who also have cardiac decompensation and auricular flutter require preliminary digitalization, otherwise the operation may be a success but the patient will succumb to cardiac failure.

The surgical risk from this operation is small indeed, but the greatest danger is ulcer of the cornea which may so resist all treatment that enucleation may have to be done. The patient should be informed of this danger beforehand. Usually, however, this hazard will not deter him from submitting to surgery, in his desperate search for relief from pain.

RELIEF OF GLOSSOPHARYNGEAL NEURALGIA

The relief of pain from glossopharyngeal neuralgia is required infrequently, as this type of neuralgia is uncommon. It is not to be confused with trigeminal or superior laryngeal neuralgia.

After all causes of pain in the throat, such as organic diseases of the pharynx, neck, posterior cranial fossa, etc., have been eliminated one is justified in considering the pain due to glossopharyngeal neuralgia and in instituting treatment for this condition.

There are three methods of treatment for the relief of this type of neuralgia: Alcohol injection of the nerve near the jugular foramen, neurectomy of the ninth nerve as high up in the neck as possible, and intracerebral section of this nerve.

Alcohol injection in the region of the jugular foramen is not to be attempted by the inexperienced, as the danger of paralysis of the bulb is great. For the injection the needle is inserted in front of the tip of the mastoid, from where it is passed inward and slightly upward to a depth of $1\frac{1}{2}$ inches. When the needle strikes the nerve, pain will be felt in the lateral region of the throat radiating to the eustachian tube and behind the ear.

Injection is then made with 2 per cent novocain followed by 95 per cent alcohol, described under trigeminal neuralgia, with resulting relief of pain in, and anesthesia of, the pharynx, and loss of taste on the posterior third of the tongue.

This method and neurectomy of the ninth nerve may afford relief varying from six months to two years, after which the pain recurs. Intracerebral section of the glossopharyngeal nerve effects a permanent cure from the pain.

RELIEF OF SUPERIOR LARYNGEAL NEURALGIA

Superior laryngeal neuralgia is even more uncommon than the glossopharyngeal type, from which it must be differentiated. The former must not be mistaken for tuberculous or malignant disease of the larynx and epiglottis, or for the gastric crises of tabes.

In alcohol injection for the relief of pain from this form of neuralgia, only the internal branch of the superior laryngeal nerve is injected. With the left index finger on the greater cornu of the hyoid bone (Fig. 119), the needle is inserted in the midline between the superior laryngeal margin and the hyoid bone and is carried laterally through the thyrohyoid ligament, which offers considerable resistance toward the cornu of the hyoid bone. The internal branch is then located by probing with the needle until pain is felt in the side of the neck shooting up to the ear, and from the side of the

thyroid cartilage darting up to the angle of the jaw. Successful injection with novocain and alcohol produces anesthesia

Fig. 119.—Injecting the superior laryngeal nerve.

of the larynx and epiglottis, and relief from pain. Neurectomy of the internal branch gives the same results as alcohol injection.

RELIEF OF OCCIPITAL NEURALGIA

Occipital neuralgia is not common. When severe pain is experienced in back of the neck radiating over the occiput into the parietal region associated with hyperesthesia of the scalp, neuralgia of the great occipital nerve may be the cause, but rheumatic myositis of the neck muscles, arthritis deformans, caries or tumors of the first or second cervical vertebra and hysteria must be ruled out.

The pain of occipital neuralgia will usually be relieved by external heat and counterirritants, as mustard plaster, to the occipital region, or alcohol injection into the great occipital nerve.

For alcohol injection, the needle is inserted vertically downward to the bone at the point of emergence of the nerve midway between the mastoid process and the first cervical vertebra, and about $\frac{1}{2}$ inch below the level of the occipital protuberance. Subsequently there will be anesthesia of the scalp in the occipital region and relief from pain in that region.

RELIEF OF PAIN FROM SLUDER'S NEURALGIA

Relief of pain from Sluder's neuralgia may be obtained by extirpation or cocainization of the sphenopalatine ganglion.

The treatment of this form of neuralgia is most efficiently performed by the nose specialist and the reader is referred to the literature on rhinology for further information on this subject.

CLINIC OF DR. ROBERT O. RITTER

ST. LUKE'S HOSPITAL

RELIEF OF LUMBAGO AND SCIATICA

IN adult life there is no more common complaint than backache with or without sciatic radiation. The majority of patients with backache have, without a thorough examination, been treated for lumbago or sciatica. These two complaints and the disabilities resulting from them are serious problems which confront the general practitioner, the orthopedic and the industrial surgeon. Any patient seeking treatment for backache or sciatic pains requires a complete and thorough history and physical and x-ray examination. Such an examination and history will, in most cases, lead to the discovery of the causative pathology. Only then can rational therapy be instituted.

There are many anatomic variations in the lower spine which may at times produce pain and disability. Among these are sacralized fifth lumbar transverse processes (Fig. 120), spina bifida occulta, abnormal articulations, an abnormally oblique lumbosacral angle, spondylolisthesis (Figs. 121, 122), pronounced hollow back and static factors. Flat feet and short Achilles tendons produce fatigue of the lumbar muscles, and often a severe back strain. Poor sitting posture in a chair or in an automobile during a long drive often causes backache.

Genito-urinary, gynecological and neurological conditions should be investigated and eliminated. Pains in the lumbosacral region and over the sacrum should make one think of disease of the prostate and seminal vesicles. In women static backache often cannot be distinguished from that due to pelvic disorders. The gynecologist should be consulted in all ques-

Fig. 121.—x-Ray of A. S., showing fifth lumbar vertebra slipped forward into the pelvis.

Fig. 122 —Complete fifth lumbar spondylolisthesis. Two large tibial grafts were inserted across the lumbosacral joint

tionable cases. A careful examination will eliminate many radical intrapelvic operations. However, it has been our experience that uterine trouble is more often ruled out than not.

Pain in the back is present in certain diseases of the nervous system. Tabes, cord tumors, disease of the cord itself, and peripheral nerve disturbances are to be ruled out. During the last year four patients, one man and three women, entered our clinic because of severe pain in the low back. Or-

Fig. 123.

Fig. 124.

Fig. 123 —J. P. Sciatic scoliosis with arthritis. Not relieved by palliative measures.

Fig. 124 —J. P. After trisacral fusion. No return of symptoms after four years.

thopedic and x-ray examinations failed to explain fully the cause for all the complaints. A thorough neurological examination revealed a multiple sclerosis in each case.

Metastatic disease of the spine and pelvic bones causes extreme pain. Pain due to malignancy is not relieved by rest on a rigid bed or by other therapeutic measures as is the pain from any other cause.

There can be no doubt that backache and sciatic pains are very often due to the presence of an actual osteo-arthritis

of toxic or infectious origin. (Figs. 123, 124.) They may also be due to age and to certain back-straining occupations.

When an inflammatory process is added to a mechanically unstable joint, pain and disability follow. The pain may come on suddenly or insidiously, and may radiate down one or both sciatic nerves, the gluteal nerves or down the front or sides of the thighs. It may be so severe as to be immediately disabling, as in sudden twists of the body or when a heavy object is lifted. In many instances where there has been an injury, the pain does not appear until a day or two later. The reason for this very common occurrence has not been fully explained. By some it is considered a ligamentous strain followed by edematous changes or a tear of muscle fibers with resulting spasm. By others it is regarded as a myofascitis of a rheumatic nature. If the x -ray shows arthritic changes they are due either to disease or long continued strain or both.

Many cases of disease and strain of the sacro-iliac joints occur but the lumbosacral is more often the site of the lesion. In some cases it is difficult or impossible to determine in which of these joints the trouble exists. However, a careful physical and x -ray examination will usually lead to a good working diagnosis.

Pain along the course of the sciatic nerve occurs in both sacro-iliac and lumbosacral lesions. If it is unilateral, either may be involved. If bilateral, the lesion is usually in the lumbosacral joint. Gaenslen's sign for sacro-iliac lesions is very reliable. "Hyperextension of one hip with the opposite knee and hip acutely flexed to fix the lumbar spine, including the lumbosacral joint. Pain is present only in the sacro-iliacs, ruling out lumbosacral cases."

The etiology of any given case will govern the treatment. This may be either conservative or operative.

All acute painful cases with or without radiating pains should be put at rest on a rigid bed, and some form of physical therapy, such as heat and massage, begun. Large doses of salicylates are beneficial. Head and pelvic traction or a plaster cast may be necessary to relieve muscle spasm in a

certain number of cases. All foci of infection should be carefully sought and removed. This is especially true in the intestinal tract, teeth and tonsils. However, teeth should not be extracted just because they are devitalized. (Fig. 125.)

In cases of low backache, where mild static faults are present, the skeletal alignment is corrected with supporting corsets or braces. Graduated exercises, massage and physical therapy are of value. In sacro-iliac strains without extreme

Fig. 125.

Fig. 126.

Fig 125.—J. C. Sciatic scoliosis. Relieved by clearing up infected teeth and gums, and palliative measures.

Fig 126 —S. K L. Scoliosis. Severe lumbago. Relieved by palliative measures.

pain or muscle spasm, a firm adhesive plaster strapping gives immediate relief. The one disadvantage of adhesive is that some skins are easily irritated by it. For this reason a well fitting, non-elastic corset is preferable. In a great many cases of painful sacro-iliacs an ordinary belt such as men wear, buckled tightly around the pelvis just above the trochanters, gives prompt relief. (Fig. 126.)

In some cases where the disability comes on suddenly following an injury, manipulation under complete anesthesia and

rest on a rigid bed for a few days are sufficient. Other more severe cases require immobilization with a cast or brace.

In the many cases not relieved by conservative measures, surgery becomes necessary. These are the chronic cases in which there is definite x-ray evidence of disease or deformity. In a certain number of cases, affection of the lumbosacral or sacro-iliacs cannot be differentiated. In these, all three joints should be ankylosed. For the lumbosacral arthrodesis the Hibbs technic has been quite generally used with the addition of two large tibial grafts. These grafts are cut from the flat surface of the tibia. One end of each is cut on an angle that just fits the lumbosacral angle. The grafts are fitted in edgewise, one on either side of the denuded spinous processes, with the medullary surfaces together. In all cases where this type of graft has been used, a very heavy mass of bone has been formed, and no failure of ankylosis has occurred. Such has not always been true where pieces of ilium were used.

The Smith-Petersen operation is adaptable to one or both sacro-iliacs, but not to the combined or triple arthrodesis. For the triple arthrodesis the extra-articular operation on the sacro-iliacs is the method of choice.

Operation is certainly advisable if the disability is a real handicap, especially in a wage earner. The operation is as safe as any major surgery, but it has a disadvantage in that it requires eight to twelve weeks for a solid ankylosis to take place.

When the excellent results from operative, as compared to nonoperative, treatment are compared, we feel that surgery is more conservative and time saving for the patient than mechanical treatment.

CLINIC OF DR. LOUIS T. CURRY

COOK COUNTY HOSPITAL

TREATMENT OF EARACHE

EARACHE (otodynia, otalgia) is caused by pathology in the middle ear, the external ear or the internal ear, or is referred from neighboring structures in the mouth, pharynx, larynx or nose. Earache is characterized clinically by pain in the ear region and pathologically by stimulation of the complicated sensory nerves of the ear mechanism.

As a foundation for this discussion, I shall first briefly summarize the sensory innervation of the ear mechanism, as taken from the anatomies of Cunningham and Spalteholz, and then proceed with a consideration of earache, its differential diagnosis and treatment.

Sensory innervation of the ear mechanism:

1 In the ear itself.

(A) External ear.

1. Auricle.

(a) External surface.

- (1) Auriculotemporal nerve, from mandibular branch of fifth nerve, supplies upper half.
- (2) Great auricular nerve, from C-2 to C-3 of cervical plexus, supplies lower half.

(b) Cranial surface.

- (1) Lesser occipital nerve, from C-2 to C-3, supplies upper half.
- (2) Great auricular nerve, from C-2 to C-3, supplies lower half.

2 Scalp behind ear—lesser occipital and great auricular nerves.

3 Zygomatic region—auriculotemporal nerve from mandibular fifth.

4 Internal auditory canal and drum membrane.

- (a) Auriculotemporal nerve from mandibular division fifth

supplies external auditory canal and external surface of the ear drum.

- (b) Auricular branch from close below ganglion jugulare of vagus (Arnold's nerve) supplies concave surface of auricula and external acoustic meatus, and communicates with glossopharyngeal nerve.

(B) Middle ear.

1. Tympanic plexus supplies mucous membrane of tympanum and mastoid cells. Tympanic plexus is formed by tympanic nerve (from petrous ganglion of glossopharyngeus nerve) which enters the tympanum where it is joined by carotico-tympanic branches from the carotid sympathetic plexus on the internal carotid artery and a twig from the genicular ganglion of the facial nerve.

(C) Inner ear.

1. Supplied by two divisions of the specialized auditory nerve—cochlear and vestibular.

II. Neighboring structures.

- (A) Otic ganglion: Fibers of tympanic branch of glossopharyngeal nerve reunite with small nerve from genicular ganglion of facial nerve (ramus anastomaticus cum plexus tympanico) to form the lesser superficial petrosal nerve. This nerve eventually ends in the otic ganglion on the trigeminus nerve.

- (B) Sphenopalatine ganglion: Greater superficial petrosal nerve (mostly sensory fibers) from genicular ganglion of facial nerve unites with deep petrosal nerve from sympathetic on internal carotid artery to form nerve of pterygoid canal (O. T. vidian nerve). It passes through sphenopalatine ganglion and supplies mucous membrane of soft palate.

- (C) Pharyngeal plexus: Pharyngeal branches of glossopharyngeal nerve supply mucous membrane of pharynx. These combine with pharyngeal branches from ganglion nodosum of the vagus nerve and the superior cervical ganglion of the sympathetic to form the pharyngeal plexus.

(D) Tongue and tonsils:

1. Lingual nerve from mandibular branch of fifth nerve supplies the anterior two thirds of the tongue, the mucous membrane of the side wall and the floor of the mouth. The chorda tympani from the facial nerve is carried in the lingual nerve.
2. Terminal branches of the small glossopharyngeal nerve supply the posterior third of the tongue and the tonsils.
3. Vagus nerve sends fibers to the base of the tongue

(E) Larynx and epiglottis.

1. Glossopharyngeal nerve supplies anterior surface of epiglottis.
2. Superior laryngeal nerve (internal branch from vagus) supplies mucous membrane of larynx and passes upward to epiglottis and base of the tongue.

From this sketchy summary of the complex ear innervation one concludes that earache may arise from stimulation of C-2 and C-3 of the cervical plexus and cranial nerves V, VII, VIII, IX and X.

Earache: Its differential diagnosis and treatment.

I. Aural pain from disease in the ear mechanism.

(A) Middle ear disease causing pain.

- (1) Acute catarrhal otitis media.
- (2) Acute serous otitis media.
- (3) Acute suppurative otitis media.
- (4) Acute mastoiditis.
- (5) Chronic suppurative otitis media and chronic mastoiditis.
- (6) Chronic adhesive middle ear catarrh.
- (7) Blue ear drum.

1. **Acute Catarrhal Otitis Media.**—As a rule acute catarrhal otitis media is a complication of acute coryza. The patient notices a fulness in the ear which may later become severe. There may be crackling and buzzing noises in the affected ear. The ear drum usually shows some congestion of the blood vessels especially over the handle of the malleus. There is usually some diminution of hearing. The treatment consists in the treatment of the cause.

2. **Acute Serous Otitis Media.**—Acute serous otitis media arises when acute catarrhal otitis media progresses with the formation of serum in the tympanum. If the tympanum fills, the ear drum appears unusually clear, although the patient complains of fulness in the ear and the hearing is impaired. If the serum partially fills the tympanum, its upper edge may be seen as a hair line shining through the drum head. The pain is in the ear and usually disappears in a day or two. Treat the underlying cause. Four or 5 drops of warm 5 per cent carboglycerin may be instilled in the aching ear every two or three hours for relief of the pain. Application of heat is usually comforting. Hot dressings, hot water bag, electric pad or the incandescent light may be used. If the serum is not absorbed in a few days, it is advisable to perform a myringotomy with careful antiseptic precautions. The serum is then blown out of the tympanum by inflation through the

eustachian tube. Inflations may be done in three ways: (1) Valsalva method—patient holds his nostrils, closes his mouth and employs forcible extirpation; (2) Politzer bag—blast of air is shot into one nostril while closing the other at the time patient is asked to say K or swallow a sip of water; (3) eustachian catheter—catheter passed through nose below inferior turbinate and inserted into eustachian opening. Through catheter blast of air is applied, blowing secretion from tympanum. Auscultation tube from affected ear to ear of operator is necessary to hear when this is accomplished.

3. **Acute Suppurative Otitis Media.**—Acute suppurative otitis media is the most frequent cause of earache. Actually this condition is severe, acute, advanced catarrhal otitis media. Therefore, it usually follows head colds or one of the exanthemata. The pain is severe and is felt in the ear. It is usually continuous but may have exacerbations. It is usually worse at night. The pain is relieved, as a rule, if the ear drum ruptures or if a paracentesis is done. With severe infections, the earache may continue for several days even after drainage has been given. The discharge may be serous to purulent with any degree of intermixture. It may be slight or profuse. Before rupture or opening of the ear drum, the drum head may be generally red to very red and bulging. Blood vesicles may cover the ear drum and fill a large portion of the external auditory canal. There is usually an elevation of temperature and a decided defect in the hearing.

Treatment.—1. External heat applied to the ear is the best method of relieving the earache. This may be applied by means of a hot water bag, moist hot dressings or an electric pad. Opium for relief of earache is contraindicated because it may mask the progress of the disease.

2. Ear drops for relief of pain are prescribed by many otologists. The favored prescription is phenol and glycerin (1:20). This mixture is to be used warm in the aching ear every two or three hours (3–5 drops).

3. *Myringotomy.*—The ear drum must be opened as soon as any bulging of the drum membrane is seen, or sooner if

the earache continues for twenty-four hours or longer, even in the absence of bulging. Mastoiditis and intracranial complications occur less frequently where early paracentesis is done. Paracentesis of the ear drum is carried out, using proper antiseptic precautions, with an anesthetic, either local or general.

Local Anesthetic.—Equal parts of phenol, menthol and cocaine hydrochloride are used. This thin paste is applied sparingly with a small cotton applicator to the bulging area of the ear drum. It is well to warn the patient that the first touch hurts. The swab is held in place as long as the patient can bear it, which is usually a few seconds. The same procedure is continued until the applicator can contact the inflamed ear drum without much discomfort for a minute or two. The incision is then made through the bulging area of the ear drum, which should appear white if properly anesthetized with a light paracentesis knife. If there is no bulging, the incision is made in the posterior quadrant of the ear drum. In certain types of influenza ears, the ear drum cannot be seen because of blebs. These can be opened only by guess. With gentleness and care, an experienced surgeon can insert the knife through the blebs and toward the ear drum until the point of the knife gently strikes the promontory without harm. I have found no need for extensive incision of the ear drum. If the tympanum continues to fill with pus, the small incision enlarges with the infection. If drainage is slight, the small or large incision closes quickly and another opening may be required.

General Anesthetic.—Nitrous oxide or ethylene are ideal anesthetics for myringotomy. The advantages are evident, but there are drawbacks. The cost is greater for a general anesthetic, since more time is required of the physician, an anesthetist's services are required, and there is a hospital bill. Another handicap to the general anesthetic is that the indications for paracentesis often arise during the acute exanthemata while the patient is quarantined.

Without Anesthesia.—Myringotomy may be performed without anesthesia, but the operation causes severe pain.

Earache may disappear after drainage has been given, to reappear if any blockage takes place. This can be remedied by instilling a few drops of hydrogen peroxide into the meatus. Thus drainage is reestablished. When earache continues after paracentesis, external heat is applied.

The draining ear should not be plugged with cotton. The external canal must be kept clean by dry wicks, frequently changed, or by frequent wiping of the external meatus. When the discharge is very thick, it may be cleaned out by gentle syringing with warm boric or soda water. At night, the ear toilet is best cared for by layers of gauze over the pinna which are held in place by a hair net tied under the chin. The cavum conchae and incisura intertragica must be kept clean with warm saline solution bathing daily and covered with a thick layer of zinc oxide ointment. If this is not done, the patient often develops a painful dermatitis from the irritating discharge.

4. Acute Mastoiditis.—Acute mastoiditis is usually a complication of acute suppurative otitis media. Pain over the mastoid, often present when myringotomy is done, usually disappears after drainage is instituted. Pain over the mastoid, significant of acute mastoiditis, usually starts after the ear has been draining for two or three weeks. It may, however, be present in the beginning of the otitis media and persist until relieved by surgical intervention. In other cases, it may appear after the ear discharge has ceased. There may be changes in the soft parts over the mastoid process and tenderness to pressure, especially over the antrum, the tip or the emissary vein. In adults there may be no tenderness when pressure is applied over the mastoid or alterations in the soft structures even in the presence of an acute mastoiditis.

Mastoid pain is usually worse at night. If the patient with an acute otitis media has pain at night in the mastoid area and a discharge which is becoming more purulent, formation of a mastoid abscess is indicated. Pain may also be

caused by subperiosteal abscess or Bezold's abscess. The pain is less after the abscess forms than during its formation. Tenderness over the abscess is noted upon palpation. The subperiosteal abscess may form posterior, superior or anterior to the auricle. A Bezold abscess is caused by a rupture of a mastoid abscess through its tip. These may appear superior, in or below the sternocleidomastoid muscle. Occasionally they appear posterior or anterior to this muscle.

Treatment.—Early mastoid pain is treated by hot applications as previously described. Some otologists prefer ice packs or ice coils, feeling that an abscess is more often avoided. The cold aids in control of the pain.

The indications for operative interference in acute mastoiditis differ for the small child and for the adult.

In a small child operative interference is indicated:

1. When subperiosteal abscess develops if the ear has previously had proper treatment and drainage.
2. If symptoms of threatened intracranial complications appear, as meningismus, meningitis, lateral sinus thrombosis, brain or cerebellar abscess.

In an older child or in an adult the indications for operation are:

1. As above.
2. As above.
3. If earache continues for seven to ten days after proper treatment has been instituted.
4. If the discharge continues to be purulent after proper treatment and shows no evidence of diminishing for four weeks.
5. If the patient continues to have rather high fever and palpable changes over the mastoid for two weeks, even though proper treatment has been given.

The operation indicated is a simple mastoidectomy which has for its object the drainage of the mastoid abscess. Usually in adults the external wall of the antrum is opened, although the antrum is not necessarily the location of the abscess. In

infants, since mastoid cells have not developed, the operation is more properly called an antrotomy.

Recurrent Mastoiditis.—This term is applied to patients who have had simple mastoidectomies and develop acute suppurative otitis media. The pus backs up into the antrum which is immediately below the soft parts behind the auricle. An abscess may develop in this region which causes the pain typical of any abscess. After using heat, if the abscess does not subside, it is opened and drained as any other abscess, after which the symptoms of otitis media usually promptly subside if the previous mastoidectomy has been complete. Occasionally it is better to expose the mastoid cells area and seek for further infected broken-down cells which should be eradicated.

Gradenigo Syndrome.—This properly comes under the heading of mastoiditis. Severe headache referred to the side of the head in the region of the affected ear, purulent otitis media and paralysis of the sixth cranial nerve on the same side are the cardinal symptoms of this syndrome.

Treatment: Most otologists agree that at least a simple mastoidectomy is indicated when symptoms of this syndrome are present. Others insist upon drainage of the petrous tip cells, which is a difficult and dangerous procedure. Swelling of the gasserian ganglion which causes the sixth nerve to be put on a stretch is one of the theories given for paralysis of this nerve. In these conditions I favor conservative treatment as taught me by Dr. George E. Shambaugh. We used conservative treatment on a woman with chronic suppurative otitis media accompanied by Gradenigo's syndrome five years ago. She recovered and has been free from recurrence since. I have treated twenty patients successfully by conservative treatment, *i.e.*, simple mastoidectomy and keeping the wound open until dry. One of my patients died. His pain continued in the side of the head after the mastoid operation. Drainage continued for one month, after which the pain subsided and the drainage ceased. He moved to another city, had a recurrence of headache, was operated and died.

I do not know the nature of the operation performed. Recently I treated a boy with typical symptoms of this syndrome, but his otitis media was mild. His aural discharge stopped, his headache subsided and his lateral rectus paralysis disappeared in two weeks. I decided not to operate upon his mastoid. His ear is now dry, his drum membrane healed and he is free from headache but his lateral rectus paralysis has reappeared. He has been under observation for three weeks since his ear drum became normal. The outcome is to be awaited.

5. **Chronic suppurative otitis media and chronic mastoiditis** are not as important from the standpoint of earache as they are from absence of earache and danger of intracranial complications. Chronic suppurative otitis media may be discussed under two very different types:

1. Inflammatory changes limited to mucous membrane of the middle ear chambers. This is misnamed the "nondangerous type," but should be called the less dangerous type.

2. Changes in the middle ear associated with a bone-invading process. This is properly called the dangerous type.

In the first type, pain is rarely a symptom if the ear is kept clean and properly treated. Occasionally a polyp forms which blocks drainage and causes earache. The treatment is to remove the polyp with an ear snare or cautery and reestablish proper drainage. Silver nitrate in solution or fused on a probe, or chromic acid fused on a probe may be used to cauterize. In using the chromic acid bead, the bead should be cherry red and not black in color to cauterize properly.

Individuals with chronic otitis media sometimes develop an acute otitis media in the same ear which gives the otalgia of that disease. The treatment is practically the same except that operative interference may be indicated earlier because of the greater damage of intracranial complications.

In the second type of chronic suppurative otitis media, earache is more common but seldom severe. It consists usually of a dull ache in the ear or is referred to the side of the head as a heavy feeling. Occasionally the pain may be deep

seated or boring in character. Its significance is quite important, since it may indicate a threatened intracranial invasion. In this type of ear disease we deal with sequestration, caries and cholesteatoma. Usually the treatment leads to radical operative treatment, unless the hearing in the opposite ear is more seriously affected. The radical mastoid operation is practically never done because of pain. Therefore, a description of it is not in order here.

The complications of chronic suppurative otitis media should be mentioned, but earache is not a prominent sign in any of them. They may intervene without any sign of earache or there may be a warning sign of a heavy feeling in the side of the head. Very rarely is there any severe pain.

INTRACRANIAL COMPLICATIONS OF CHRONIC SUPPURATIVE OTITIS MEDIA

1. Labyrinthitis, which may be circumscribed or diffuse and serous or suppurative.

2. Lateral sinus thrombosis.

3. Meningitis, which may be serous or suppurative and circumscribed or diffuse.

4. Brain abscess.

5. Cerebellar abscess.

6. **Chronic adhesive middle ear catarrh** occasionally causes dull or even sharp earache. Prophylactic treatment of this condition is most important, because if neglected it causes permanent impairment of hearing. Removal of tonsils and adenoids early, in children suffering from repeated ear infection, is the best prophylaxis.

7. **Blue ear drum** is a rare condition in which the tympanum is filled with a thick chocolate-like secretion. Inspection shows the blue ear drum. It causes more of a fulness than an earache. Treatment is the same as for serous otitis media.

(B) External ear disease causing pain.

1. Inflammations

(a) Furunculosis

- (b) Eczema
- (c) Fungi
- (d) Erysipelas
- (e) Subperichondrial abscess
- (f) Herpes zoster auriculæ
- 2. Foreign bodies
 - (a) Inanimate
 - (1) Impacted cerumen
 - (2) Vegetable as peas, corn, beans
 - (3) Miscellaneous—stones, paper, pencils, etc.
 - (4) Epithelial plugs
 - (b) Animate
 - (1) Insects
 - (2) Worms
- 3. Trauma
 - (a) Burns
 - (b) Frostbite
 - (c) Pugilist ear
 - (d) Wounds—gunshot, stab, etc.
 - (e) Rupture of ear drum, penetrating wound, blow, skull fracture
- 4. New growths—carcinoma
- 5. Granulomata
 - (a) Syphilis
 - (b) Tuberculosis
 - (c) Blastomycosis
 - (d) Actinomycosis.

(a) **Furunculosis** of the external meatus is always located in the outer membranous portion of the meatus and the diagnosis can nearly always be made by eliciting pain by pressure upon the meatus or by movement of the auricle. If the furuncle is deeper in the meatus and large, it may push the auricle forward, simulating a subperiosteal abscess in acute mastoiditis. Both conditions may be present. Often furunculosis is associated with an acute or chronic suppurative otitis media. In these instances the signs of inflammation as given above are found in the external portion of the meatus and the indications of the middle ear disease are discovered with speculum and by means of tuning-fork examination.

The pain in furunculosis is often severe and out of all proportion to the clinical findings. It is referred to the ear and the side of the head, and often mastication is painful.

Treatment.—Prophylaxis. "Avoid scratching the ears with anything but the elbows" is trite but excellent advice. For itching ears use salicylic acid in alcohol (1:10 per cent). Swimmers may avoid furuncles if boric acid and 95 per cent alcohol (4:100) is used to dry the meati after coming out of the water.

The active treatment of furunculosis should always be conservative. My preference is to carefully wipe out the meatus and fill with $\frac{1}{2}$ of 1 per cent yellow oxide of mercury in water-free lanolin. This procedure should be repeated daily by the physician until the furuncle ruptures or subsides. At home the patient should use wet hot dressings of generous size over the auricle constantly if the pain is severe. Sedatives may be prescribed, as acetylsalicylic acid, acetanilid, salicylates, even morphine. With this treatment the patient suffers usually two or three days, but recurrences are rare. In infants the same treatment may be used. Phages and anti-virus may be used. Five per cent carbol glycerin, 4 or 5 drops every three or four hours, may be tried in the ear early. When the furuncle has developed to a distinct white head, it may be incised with a cataract knife, using proper antiseptic precautions. Roentgen rays may be tried when the furuncle does not point and great induration is present. The dosage is usually about one-third erythema dose. Wick treatment is used by some otologists. Moist wicks are used, saturated with a weak solution of aluminum acetate or other astringent drug. Dry treatment is preferred by some. This may be carried out by blowing boric acid powder into the meati.

For recurring furuncles, good results are often obtained with autogenous vaccines.

(b) **Eczema** of the auricle and external meatus may occur in any form, but does not produce earache unless complicated by furunculosis or perichondritis. Itching is the chief symptom. The treatment (rather unsatisfactory) is both general and local, but does not fall properly under the title of this paper.

(c) **Fungi (Otomycosis).**—A soft, dirty, grayish, salve-

like substance may form in the external meatus. When this is removed, the canal wall appears raw and bleeds easily. This material recurs in a few weeks after cleaning if the canal is not treated. Subjectively the patient complains of a fulness, stinging or itching in the ear. The infection may be resistant to treatment. Usually a mild parasiticide is prescribed, as 2 to 10 per cent salicylic acid in 95 per cent alcohol. The ear is wiped out fairly dry and the patient instructed to fill the canal once or twice daily with the mixture. Hyposulphite of soda (0.2 in 30) may be tried. In a few days the fungus growth may be destroyed, after which it is well to have the treatment continued at weekly intervals for some time to prevent recurrence.

(d) **Erysipelas** of the auricle does not differ from erysipelas in other parts of the body. The pain may be intense in the involved region and the disease presents its redness, swelling, raised, red border and fever.

Treatment.—Prophylaxis and isolation from surgical and obstetric patients until lesions are healed. Locally, the treatment is ultraviolet irradiation of the area involved and of the normal adjacent skin at least 2 inches beyond the border. Roentgen rays are used not over one-fourth erythema dose. Evaporating lotions are applied ice cold by means of uncovered compresses. A 50 per cent solution magnesium sulphate may be used. Erysipelas antiserum preceded by an intracutaneous test of 0.1 cc. of the serum diluted 1:10 may be used. If the test is negative within fifteen minutes, the remainder of the contents of the ampule may be injected. The dose may be repeated daily for three days. If the test is positive, it might be well to try convalescent erysipelas serum rather than the serum derived from the animal, in amounts varying from 40 to 100 cc. Fever symptoms are treated as indications arise. Hypnotics, often paraldehyde (teaspoonful in a half glass of water), are used for obstinate insomnia, and stimulants for collapse.

(e) **Auricular perichondritis or subperichondrial abscess** is ushered in with pain over the auricle affected, the

pain depending on the severity of the infection and the area involved. The treatment depends on the extent of the lesion. If a relatively small area is involved, conservative treatment with wet dressings is indicated. If it is more extensive, it is best to incise early and drain with a small gutta-percha drain. Warm dressings are applied and the drain changed daily. The bandage should be rather tight. The principle is to save as much cartilage as possible because of the rapid cartilage necrosis and the consequent disfiguring deformity.

(f) **Herpes Zoster Auriculæ (Koerner's Syndrome: Hunt's Syndrome).**—Herpetic eruption over the concave surface of the auricula and the external acoustic meatus may be associated with facial paralysis. The pain is burning in character. Since the pathology is thought to be a geniculate ganglion neuritis, the treatment is that of any neuritis. Remove foci and give salicylates. One to 5 per cent ammoniated mercury ointment may be tried locally.

Foreign Bodies.—Impacted cerumen is the most common foreign body but causes the least pain. If there is any pain, it is usually a fulness in the affected ear or occasionally an unpleasant sensation of something striking the ear drum with a change of position. Treatment consists in removal by syringing with an ear syringe, using warm water. The stream should be directed toward the upper portion of the canal while the auricle is pulled upward and backward. If several attempts prove unsuccessful, the patient is instructed to use normal salt or soda water in the ear twice daily and to return for a second syringing. The ear hook may be used if the operator is careful and skilful enough not to injure the delicate epithelium of the external meatus. The hook is placed over the cerumen, turned, and gentle traction is exerted. The cerumen, if dry and hard, is adherent to the dead surface epithelium. Therefore, the patient should be cautioned to hold still, and to swear, not jump, if hurt.

Vegetable foreign bodies, as peas, corn and beans, may swell after lodging in the external meatus and thus cause con-

siderable pain. They can usually be syringed out if found early. Otherwise they must be removed with a hook or ear forceps. Great care must be exerted to do no harm in treating foreign bodies. It is far better to leave any foreign body in the meatus than to injure the epithelial lining or push the object through the ear drum while trying to extract it.

Stones, paper and miscellaneous materials are often found in the external ear and may or may not cause earache. They are removed as described. Hard foreign bodies, when medial to the isthmus of the meatus, may be difficult or impossible to dislodge. A modified radical mastoid operation may be necessary. A considerable number of serious complications are seen each year because of clumsy attempts at removal of foreign bodies.

Epithelial plugs (cholesteatoma-like accumulations) are rare in the external auditory meatus, but may cause earache and impaired hearing if present. The treatment is to remove the mass by mechanical means or by a solution which is dehydrating, as 1 per cent salicylic acid in alcohol. After the canal is cleaned, the granulations should be treated until healed.

Live insects may be very painful as they hop up and down on the ear drum. A few drops of alcohol or chloroform quiets them, after which they are easily syringed out. In emergency, pouring water into the meatus will subdue these insects.

Trauma.—Burns demand no special consideration, as they are treated the same as burns elsewhere.

Frostbite frequently affects the auricles because of their exposed location. Instead of painful ears, the ears feel numb. They should be rubbed with snow or cold hands. This treatment restores the circulation. When the ears become painful they are treated as burns.

A prize fighter ear is usually caused by a blow on the auricle, or by a twist. Pain depends upon the amount of blood accumulated beneath the perichondrium, but is usually not severe. If the effusion is small, it should be treated conservatively and will absorb with a pressure bandage. If the

blood clot is larger, free incision through the perichondrium is necessary and a pack is inserted as in perichondritis.

Wounds need no special description.

Traumatic rupture of the ear drum by puncture wound, a blow on the ear, explosions, or skull fracture may be accompanied by severe pain in the ear. Treatment is to control the hemorrhage, if necessary, by sterile tampon. In most cases all that is necessary is to prevent infection to the middle ear by using sterile cotton in the external meatus. Treat middle ear suppuration if it occurs.

New Growths.—Epithelioma may attack the auricle or meatus. Pain is not a prominent feature. The treatment does not vary from the treatment of carcinoma elsewhere. Early excision or diathermy is indicated. If seen later, x-ray and radium may be tried. If the temporal bone becomes involved, the earache is one of the most terrible of pains and the treatment is unsatisfactory.

Endothelioma occurs in the ear usually secondary to parotid involvement.

Sarcomas, lipomas and neuromas are rare.

Granulomata.—Syphilis and tuberculosis may occur on the auricle, but pain is usually insignificant. Blastomycosis and actinomycosis may involve the ear and cause moderate earache. A biopsy is usually needed for the diagnosis. I recently diathermized a blastomycosis of the lobule of an ear which I felt sure was epithelioma without waiting for a biopsy report. I should have suspected blastomycosis because of the large amount of destruction in nine months' time. Iodides in massive doses daily for a long time are the sheet anchor of treatment of these mycoses.

(C) **Internal Ear Disease Causing Earache.**—Involvement of the labyrinth and brain due to middle ear disease has been discussed. There is no earache as a rule from internal ear disease caused primarily from meningitis, scarlet fever, mumps, measles, influenza or typhoid fever. There is only tinnitus.

II. Reflex Aural Pain.

Toothache frequently causes referred pain to the ear. The wisdom teeth are the chief offenders, the lowers more often than the uppers. Impacted molars which are causing otalgia may be discovered by a skiagraph. The treatment is the extraction of the offending tooth or teeth.

Acute tonsillitis, peritonsillar abscess and post-tonsillectomy infection may give rise to earache, but usually there is no difficulty in the differential diagnosis and the treatment is self-evident.

In parotitis the pain may be referred to the ear, but diagnosis is simple unless the external meatus is encroached upon so much that the ear drum cannot be examined.

Laryngitis caused by tuberculosis, cancer or other granuloma may cause otalgia. In these cases there is usually hoarseness and when the larynx is examined, the lesion is found. Biopsy is often necessary to make the differential diagnosis. Disease of the larynx causes earache by irritation of the superior laryngeal nerve, a branch of the vagus. The treatment is self-evident but one point might be mentioned. In dysphagia the superior laryngeal nerve is sometimes isolated and severed. When isolated, it is pinched gently, which causes pain in the ear and proves that the proper nerve is about to be cut. This symptom is also used as a guide for nerve block in dysphagia.

New growths in the vault of the pharynx and in the retropharyngeal region often cause earache. This pain may come from pressure on the nerves in this region or by pressure on the eustachian tube orifice, causing middle ear disease. These tumors are treated surgically or with x-ray and radium.

Other conditions causing neuralgic pain in the ear are carcinoma of the superior maxilla, cancer of the tongue (posterior third), inflammation of the gasserian ganglion, cold air, anemia, hysteria and neurasthenia. Treatment consists in treating the etiological factor.

CLINIC OF DR. CHARLES W. FREEMAN

NORTHWESTERN UNIVERSITY DENTAL SCHOOL

PAIN IN THE DENTAL FIELD

PAIN in the dental field is usually definite in character and location, and in most cases the cause can be determined and readily eliminated by the available methods of diagnosis and treatment. Occasionally certain atypical and migratory pains require careful study for accurate determination of the cause and not infrequently search must be made outside the oral cavity.

Toothache is not in any sense a modern disease nor has its incidence been greatly reduced in modern times. It is, however, a preventable disease or rather it is a symptom of a pathological disturbance which to a great extent is preventable. Dental caries is probably the most common of all diseases and at the present time is not entirely preventable, but it can be controlled. Modern dental care which includes periodic examination of the mouth and teeth with proper control of caries by fillings should prevent entirely the development of toothache.

PULPITIS

Pain known as toothache is caused by an hyperemia of the dental pulp, that highly innervated soft tissue which is entirely enclosed within a pulp canal and surrounded by dentine. Its blood supply is by way of one or several small foramina at the apex of the tooth, a fact which precludes the establishment of collateral circulation, and consequently tends to complete infarction when the pulp is seriously disturbed.

When an inflammatory process develops as a result of irritation—traumatic, chemical, thermal or bacteriologic—the en-

closing dentine permits no expansion of the inflamed tissue and a sharp pain ensues. Such a pain may be steady or intermittent, sharp, dull or throbbing, depending on the local factors. It may be stimulated by a single sudden irritation, beginning as a sharp stabbing pain which gradually recedes. It may be aggravated by recurrent irritations, as in thermal shock where large metallic fillings are close to the pulp, the transmission of all extreme changes in mouth temperature repeat the insult to the pulp, thus further increasing the inflammation.

A steady pain of the same general type but without recurrent external cause generally indicates a partial degeneration or necrosis of the pulp. Infection may be present or absent within the pulp at this stage of degeneration. This pain occurs most frequently at night and there is at least a partial remission during the day, although the pain may be stimulated by outside irritations. Usually, in fact, such a tooth is extremely responsive to external stimuli and the patient is inclined to favor and protect it by chewing on the opposite side and avoiding extremes of temperature within the mouth. At night the pain is likely to be throbbing and the pulse can be distinguished by waves of increased pain.

Diagnosis of the cause of these pains is made by clinical study, augmented by thermal and electric tests of the suspected pulps. Often the patient can identify the offending tooth and clinical examination reveals an all too evident cause. The *x-ray* is not often useful, since pulp changes are not demonstrated on the *x-ray* film, although in pulpitis of long standing periapical bone changes may occur sufficiently to be recorded on the film while the pulp is still vital. The *x-ray* film is also useful in discovering hidden causes such as leaking fillings, undiscovered caries and, of course, is useful in ruling out other possible sources.

Occasionally the location of the pain is not definite and if an evident cause such as open caries is not discovered, it requires a careful *diagnostic study to determine the source*. Generally a delay of a day or two will permit further progress

of the pulp degeneration with consequent definite localization of the pain and at that time any doubt as to location and cause is removed.

The causative factor in pulp irritations may be the formation of secondary dentine such as occurs in connection with severe abrasion of the teeth. This secondary calcification may be so extensive as to completely obliterate the pulp chamber, the pulp receding as the secondary calcification takes place. This is an emphasized physiological action and normally occurs without pulp irritation, but may occasionally be responsible for severe pulp disturbances accompanied by pain.

In any pulpitis regardless of the cause, the recovery of the pulp is doubtful if the pain has been of long duration. The treatment consists of the extraction of the offending tooth or the surgical removal of the pulp with subsequent treatment of the pulp canal and placement of a root filling.

PERIAPICAL INFECTION

Pulp degeneration with eventual death of the pulp by infarction may be a rapid process accompanied by mild or severe pain symptoms just discussed, or it may occur with little or no pain and may be a very gradual process extending over months. Ultimately the death of the pulp does occur and a new type of pain may result. This is the pain connected with periapical inflammation and infection, and is of an entirely different character.

This pain may begin before the pulp degeneration is completed and this makes an accurate diagnosis difficult, because one type of pain is merging into the other, consequently the pain is not typical of either pathological condition. Usually the period of transition is not prolonged, since inflammation in the periapical region causes additional disturbance to the blood supply of the degenerating pulp and complete infarction rapidly follows. It should be reiterated that both these conditions may occur as a result of irritation without infection, but even if infection is not present in the early stages it almost invariably occurs later if treatment is not given.

Pain connected with periapical infection is distinguished from pain within the pulp by the character of the pain and the reaction to external stimuli. In periapical infection the pain is definitely one of pressure, it is generally well localized and a certain tooth is sore to percussion and pressure and the tooth gives a sense of elongation due to the pressure of confined fluids in the periapical space. At this period or a little later the gum tissues over the apex of the tooth also become inflamed and sore to pressure.

A controlled inflammatory process probably occurs in the periapical region in every case in which the pulp dies or is artificially removed. If infarction of the pulp occurs without bacterial invasion or if the pulp is removed surgically by dental methods, the disturbance of the periapical tissues and the consequent pains are slight and transitory. Occasionally chemical irritation with considerable pain occurs during the treatment of a tooth with certain drugs used for sterilizing the root canal. This also is transitory unless metastatic infection occurs.

The initial periapical bone changes which can be depicted on the x-ray film are probably caused by the inflammatory reaction with pressure resorption of the bone. When infection occurs bacterial liquefaction of the bone follows and a definite bone cavity develops. Coincidentally, an inflammatory proliferation of the connective tissue of the peridental membrane occurs, and this proliferated tissue eventually becomes the so-called "granuloma" of the chronic periapical infection. The granuloma is a protective rather than a destructive tissue and serves to wall off the infection, and under favorable conditions the infection may actually be eliminated with eventual regeneration of bone.

During the early stages of the acute periapical disturbances infection is not under control and the severe pain increases and continues for several days. Unless relief is given by treatment through the root canal the infection develops to a point where evacuation through the bone relieves the severe pressure. In the occasional case the infection is controlled

by the tissue response and spontaneous recovery from the acute phase of the infective process occurs.

When the acute infection continues to the localization of pus there is usually a definite time at which the severe pain from confined infection is relieved by evacuation through the bone. The pain then becomes more generalized, but the tooth is no longer sore, for the tissues overlying the bone in the periapical region are now exhibiting the symptoms of acute infection. General toxic symptoms also increase at this stage, but such symptoms seldom occur while the pulp is still vital regardless of the amount of pain which may be present.

After localization of pus beneath the periosteum the proper treatment is evacuation of the pus by incision or if untreated, there is usually an eventual spontaneous evacuation. Any delay in drainage after localization is dangerous, for subperiosteal accumulation of pus seriously interferes with the blood supply to the bone and may result in serious bone disturbance.

Pericoronal infections about partially erupted teeth, and occasional lateral abscesses due to deep pyorrhea pockets alongside the root of the tooth may also exhibit some of the symptoms described in periapical infections. Generally the first phase of the infection with the typical soreness of the tooth to percussion is absent in such infections, since they do not begin in the apical region. They are also more likely to end in spontaneous drainage, since the initial infection is not located deep within the bone.

A large percentage of the pains in the oral cavity are of the types just discussed. Accurate diagnosis is usually possible at the first clinical examination. Occasionally observation for a day or two is necessary to determine the exact source of the pain, but since both types of disturbances are progressive in character any uncertainty may be eliminated by a short period of clinical observation. After the cause of a pulpitis or a periapical infection has been determined definite treatment is readily planned and practically always effective.

MAXILLARY SINUS INFECTION

Maxillary sinus disease is occasionally of dental origin but the initial cause is more frequently nasal. Pain in the dental field may be caused by sinus infection regardless of the original source, since the roots of the upper teeth are frequently in close proximity to the maxillary sinus. In addition to the common symptom of a general feeling of pressure in the sinus region there may be a definite sense of soreness about the teeth. This pain is very similar to a beginning periapical infection and may occasionally appear to be localized definitely in an upper bicuspid or molar tooth.

X-Ray studies may not always rule out the teeth, and pain tests are only an indication, not an accurate diagnostic aid. Adequate sinus examination by a rhinologist should be obtained in cases of uncertainty. On the other hand, a periapical dental infection may simulate a maxillary sinus infection and in any uncertainty a careful dental examination is essential. Probably a careful study of all the upper teeth should be routine procedure in all maxillary sinus infections.

UNERUPTED AND IMPACTED TEETH

Vague pains about the face and jaws are frequently attributed to the presence of embedded and unerupted teeth. No satisfactory explanation of the mechanism causing such pain has been advanced, but their removal is often recommended in the expectation of relief.

Unerupted teeth may become infected if there is direct communication with the mouth cavity and infrequently they become infected when no such communication exists. Such an infection runs a typical course and is often responsible for local pain, but it is the typical pain of local infection and is accompanied by clinical signs of infection. Pains which are intermittent in character or sharp shooting neuralgic pains are not caused by local infection about unerupted teeth.

Direct contact between an unerupted tooth and its immediate neighbor may cause a pressure resorption of the root of the contiguous tooth, thus setting up a severe pulp irrita-

tion with accompanying pain. Such resorptions can usually be identified by radiographic study and the usual symptoms of pulpitis are generally definite and well localized. Caries occurring in the partially erupted tooth or in its immediate neighbor as a result of food impaction may occasionally give the same symptoms of pulpitis. The cause is always demonstrable by radiographic and clinical examination when this does occur.

There is no valid reason to believe that the presence of an unerupted tooth in itself causes any pain, although some clinicians have expressed the belief that this does occur. It is explained on the basis of intermittent efforts on the part of the tooth to erupt, the eruptive force causing pain by pressure on adjoining structures. This hypothesis does not appear tenable, for pressure resorption occurs in advance of eruption and if bone structure is the only impediment to eruption, that bone resorption would be slow and painless. Innumerable clinical cases occur in which teeth, which are prevented from erupting, remain for years with no painful symptoms.

Vague pains and other nerve disturbances in the facial region which cannot be satisfactorily explained should not be attributed to unerupted teeth simply because they are found to be present. Careful examination may reveal the presence of caries, resorption of the contiguous tooth or pericoronal infection, but few, if any, other pains are caused by unerupted teeth. Follicular cysts occasionally develop about unerupted teeth, but they are painless unless infected. Supernumerary teeth and composite odontomes are frequently present about the jaws, but are not responsible for pain symptoms except under the same conditions which cause pain about unerupted teeth.

NEURALGIA

Pains generally classified as neuralgia may be considered as major and minor neuralgia. Major trifacial neuralgia or *le douloureux* exhibits typical symptoms and a definite diagnosis is practically always possible. Sphenopalatine neural-

gia is also typical in its symptoms and although infrequently encountered the diagnosis can generally be made on the basis of symptoms.

Minor neuralgia about the teeth and jaws is probably most often a pain symptom with a definite local cause which can be discovered by painstaking search and should not be classed as a neuralgia. Dental causes are then the most frequent sources of these pains in the regions innervated by the second and third divisions of the fifth nerve. These causes are frequently obscure and it requires a most careful survey of every possible source to determine the causative factor. This survey should include complete radiographic study of the jaws including the edentulous areas.

Such a study will include a search for dental caries, infections, retained roots, supernumerary and impacted teeth, imperfect and irritating dental restorations and any abnormality of bone structure. Disease of the maxillary sinus should be considered and ruled out as well as any nasal disturbance which might be a contributing factor.

Infrequently such pains may be caused by local nerve irritations in the region of a previous operation. Not only fractured retained root tips, but rough margins of alveolar process may be acting as local irritations. These occurrences are not common, for usually root fragments are exfoliated or encapsulated, the encapsulated fragments becoming surrounded by a low-grade chronic infection which does not cause pain. Rough margins of alveolar bone following extraction of teeth are generally resorbed or exfoliated and the tissues make the necessary adjustments without painful sequelae.

Several clinicians have reported the relief of such pains by minor operations which released small nerve filaments from the pressure of contracting scar tissue where operation had previously been performed, especially in the regions where impacted teeth or large cysts had been removed. This is a plausible explanation and possibly has some basis of fact, although such cases are so infrequent that there is considerable doubt of their actual significance.

EXTRAORAL CAUSES

Among the extraoral causes for pain in this region intracranial disturbances, especially brain tumors, must be considered as the most important. On several occasions I have been requested to remove impacted teeth for the relief of severe pain, when a more complete medical and neurological examination proved the source of pain to be a brain tumor.

Traumatic causes are usually self-evident and easily determined as the cause of pain. Tumors along the course of a nerve occasionally cause pain, but when this does occur it is a different type and not easily confused with pain of dental origin.

Arthritis of the temporomandibular joint is infrequent and the pain is definitely localized and is increased with functional movement. Pain which is due to changed relations of the structures of the temporomandibular joint, as a result of the loss of teeth or changes in occlusion due to wear, are usually referred to the region of the ear rather than the oral cavity.

BURNING TONGUE

An affection of the nerves, described as burning tongue, occurs infrequently. It is not a pain, but rather an unpleasant sensation, quite constant but with remissions. I have seen this most frequently in women during the menopause and it may probably be attributable to derangement of the entire nervous mechanism rather than to any local source. It has been suggested that the explanation may be based on electrophysical reactions induced by the presence of metallic filling in the teeth. There has been no verification of this hypothesis.

SUMMARY

The pains about the oral cavity may be grouped as:

- 1 Irritations and infections of the dental pulp.
- 2 Infections and inflammations at the root ends.
- 3 Disturbances about unerupted teeth.
- 4 Pains not of dental origin.

The diagnosis of the cause of such pains is usually possible with the available clinical, radiographic and laboratory methods. Occasional severe pains occur in which the cause is obscure and continued search may fail to reveal any local cause. When such pains are of dental origin and the proper diagnosis is made, definite treatment may be adopted which will rapidly and effectively eliminate the pain.

CLINIC OF DR. WALTER R. FISCHER

ILLINOIS MASONIC HOSPITAL

RELIEF FOR PAINFUL FEET

THE successful relief of pain in the feet requires as the first step the correct interpretation of the pain. A thorough knowledge of factors that produce pain in this part of the body is of the greatest importance for the analysis of each case presented. The need of a careful general survey of the patient cannot be too greatly emphasized. Pain in the foot may be the manifestation of some constitutional disease or the result of some local disturbance. One can distinguish only by a thorough physical examination. A systematic study should be made of the character, location, time of occurrence, duration and mode of onset of the pain together with a careful consideration of the associated factors such as systemic disease and local changes or abnormalities.

The things that must be taken into consideration in the history of every case are the age, sex, occupation, weight, the possibility of systemic disease, disturbances in posture and the elements presented by the feet themselves, along with the type of wearing apparel.

The cause of the pain varies to a great extent with the age of the individual. For instance, in the very young child one may find the cause to be a weak pronated foot due to faulty use or it may be associated with a deformity of the lower extremity such as genu valgum, knock knee, which disturbs the line of weight upon the foot. The older child or adolescent may suffer from foot strain brought on by the more

strenuous athletic games or the burden of occupation. Discomfort in middle-aged adults may result from obesity, arthritis or faulty shoes, while persons in advanced age may complain of trouble appearing as the manifestation of vascular disease. In other words, the age is more or less an index of the kind of trouble that is possible.

A very important distinguishing feature in the analysis of foot discomfort is the sex of the person. Women make up the great majority of individuals seeking relief and in a large percentage of the cases the modern style shoe is responsible for the production or aggravation of painful foot disturbances.

Occupation plays an important part in the production of pain in many ways. It may call for long hours of standing, which is usually done with the feet in a pronated position, thus weakening by exhaustion the upward pull of the adductor muscles of the foot. A patient's duty at work may require the lifting and carrying of heavy objects, walking over rough and irregular tracts of ground, or walking on hard pavements for many hours. A person who has escaped trouble for many years at a desk job may be transferred to a position that requires a great deal of activity upon the feet and as a result suffer great discomfort.

Since the functions of the foot are to support and move the body about, the influence of weight in every instance must be determined. Given a normally functioning foot with an extra heavy body superimposed, there is bound to be sooner or later a change in the comfort of the foot, and from no other cause than the additional weight burden. When the factor of excess weight has added to it the presence of a pathological condition in the foot such as for example arthritis, the symptoms of distress can be expected much earlier.

The presence of systemic disease as a source of discomfort can be only too plainly portrayed in the arteriosclerotic, the diabetic, the nephritic, the cardiac and the arthritic patient. As a point of emphasis on the importance of a careful consideration of the influence of systemic disease, suffice it to say that the most brief discussion of the manifestations of

constitutional disease in the foot would require a prohibitive length of time.

The chief elements presented by the feet alone in the production of pain can be classed as muscular disturbances, neglected sprains, inflammatory lesions and deformities. The influence of wearing apparel, since it is a most constant covering of the foot and since its shape is governed by style instead of the anatomical characters of the foot, is one of the most common factors in the production of pain and deformity. The present-day feminine type of style shoe with its high, narrow, wobbly heel, short, low, pointed vamp, is probably responsible for more discomfort than any other single factor.

The cases presented in this clinic represent disturbances in the anterior part of the foot. The pain in such instances may vary from a mere feeling of discomfort, numbness, or dull ache, to a sharp stabbing or burning or even a severe cramplike nature. It may be ill-defined and vague in its distribution over the region of the ball or it may be definitely localized in the region of one of the metatarsophalangeal joints or in one of the toes. Too, it may be associated with the symptoms of inflammation or deformity.

The treatment for the relief of pain in every instance depends upon the accurate determination of the cause of the pain and the elimination of that cause. In the obese individual one must reduce the weight; in the weak foot one must institute correct postural habits in standing and walking along with corrective exercises; while in the arthritic, the arteriosclerotic and the diabetic patient one must direct the treatment at the general as well as the local condition. A careful study of the causes of painful feet will convince any competent physician of the fallacy of focusing the attention upon the feet alone in an attempt to establish satisfactory remedial measures.

Case 1. Mrs. H. S., aged thirty-six, weight 206 pounds, height 5 feet 6 inches, housewife. On April 27, 1935 the patient complained of extreme soreness on the ball of the left foot in the region of the base of the second toe. The disturbance was of two years' duration and was always considerably

worse after a great deal of walking. The annoyance of the pain had become so severe the patient volunteered the statement that she wanted relief regardless of the type of treatment or shoe required. Examination revealed tenderness on pressure beneath the second metatarsophalangeal joint, along with limitation of plantar flexion of all the toes. The shoe constantly worn by this patient had a very narrow heel $1\frac{7}{8}$ inches high with a short low-pointed vamp. An outline of the sole of the shoe showed it to be much narrower than the bearing surface of the foot. Until one month before examination the patient had weighed 223 pounds. According to a standard weight chart her weight should have been 140 pounds. A diagnosis was made of foot strain manifested by pain in the anterior part of the foot.

The factors in the production of the pain were determined to be 83 pounds of excess weight until one month before examination and a high heel shoe with a too small compartment for the toes. A shoe heel $1\frac{7}{8}$ inches high continually throws the weight forward on the anterior part of the foot and when the toes are crowded together by the front part of the shoe their normal activity is greatly limited and limitation of motion and muscular atrophy soon follow. The function of the toes in aiding the foot in walking is seriously impaired.

The management of this case consisted of weight reduction, a low broad heel on the shoe and a wide compartment for the toes, along with exercises. Relief is invariably the rule when such changes are made. Because of the acute symptoms, it is often necessary to keep the patient off the feet for a short time in order to allow the inflammatory reaction from injury to subside. Pain in the forepart of the foot in such cases as the above may be a mere feeling of discomfort, a dull aching pain, a burning sensation or even a sudden spasmodic cramplike pain in the region of the ball and in conjunction with it there may be a numbness or tingling sensation in one of the toes.

Case II.—Mrs. A. D., aged fifty-five, weight 110 pounds, height 5 feet 5 inches, housewife. On August 10, 1934 the patient complained of an aching pain across the ball of both feet. The pain had been present for two or three months but was much worse the last fourteen days and was most noticeable in the left foot. The removal of her shoes gave no relief. Upon retiring at night the pain slowly subsided. She also complained of stiffness in her knees which was most marked after rising from a sitting position. Examination of her mouth revealed 3 gold crowns. x-Ray examination of these teeth showed all to be devitalized and abscesses at the bases of 2 of them. Manipulation of the great toe of the left foot produced pain in the region of the metatarsophalangeal joint. Her shoes were the typically conventional type with short pointed vamps and narrow heels 2 inches long.

The treatment of this patient consisted of rest periods off the feet, contrast baths, removal of all known infected teeth, and a low heel, broad toe shoe.

On August 31, 1934 she reported back for observation having carried out all previous instructions given her. She was greatly improved.

The impression of Case II was arthritis of the feet in the presence of foci of infection and faulty shoes.

Trouble is almost inevitable when the foot has added to its normal burden the presence of arthritis and a shoe that interferes with its function as a weight-bearing organ. This patient at the age of fifty-five years had arthritis in the feet and knees in the presence of definite foci of infection in the mouth. The management of such a case for the relief of pain in the feet certainly necessitates the installation of anti-arthritic measures which, of course, consist of rest, improvement of function in the feet along with physiotherapy and attention to all foci of infection. There are certain factors one must seriously consider in attempting to obtain relief for the patient with arthritis in the feet. In obese individuals, the extra burden of excess weight upon the inflamed joints must be removed to the greatest extent possible. It is needless to mention the practical good that comes from the removal of foci of infection throughout the body. The common conventional shoe so universally worn by women with its high, narrow, unstable heel and narrow pointed vamp must be promptly replaced by one that will permit more normal function in the foot and more normal distribution of the weight. The too thin sole that allows trauma from the hard present-day pavements is better replaced by a thicker one that affords more protection to the inflamed joints of the foot. In mild cases of arthritis where a flimsy type of shoe is worn, a good strong shoe with a stiff shank will often give enough relief as a single factor to increase the patient's comfort many degrees. Those individuals who have occupations that keep them for many hours upon their feet need in addition to other antiarthritic measures, rest periods during the working hours. In many cases it may be necessary for the patient to arrange

hip joints. Examination revealed marked limitation of motion in both great toe joints in all directions but especially in dorsal flexion. After careful consideration of her general condition a diagnosis of hallux rigidus due to productive arthritis of the first metatarsophalangeal joints was made. Anti-arthritic measures were instituted and for local treatment the patient was fitted with a pair of low, broad heel shoes with broad toe compartments. Underneath the great toe joint and just distal to it a wedge of leather $\frac{1}{2}$ inch thick was placed in the sole of the shoes. After a preliminary rest period to quiet the acute symptoms of arthritis the patient was allowed to walk about in the newly prepared shoes. Since she has worn the modified shoes, she has reported back a number of times in the last thirteen months and in each instance she reported that she had never been so comfortable for years.

The wedge in the sole of the shoe stiffens the sole and limits motion in the great toe joint. In such cases of hallux rigidus, Whitman mentions the use of the wedge on the inner side of the sole to stiffen it and limit motion in the great toe joint.

Case VI.—Mr. L. B., aged fifty-five. On January 28, 1933 he appeared for treatment of a "bunion" on the right foot which he said had been present for several years but had become inflamed and painful the last six weeks. Examination revealed enlargement of the great toe joint of the right foot with a reddish circular area on the skin of the median part of the joint. The first impression of this case was that the lesion presented was due to a tight shoe. Warm moist applications and rest without the shoe made little change in the condition. A thorough examination of the patient was then made and revealed the following findings: Blood pressure, systolic 162, diastolic 88; blood sugar 333.2 mg. per 100 cc. of blood; urine showed 1 plus sugar; condition of cardiovascular system showed evidence of arteriosclerosis. Prompt attention was then given to his diabetes and arteriosclerosis with the result that he improved. He was not seen for two years. He returned for further treatment on April 23, 1935. At this time there was definite gangrene of the toes of the right foot. On May 3, 1935 his right leg was amputated because of spreading gangrene.

The significance of this case is the fact that the patient totally unaware of the presence of arteriosclerosis and diabetes was seeking relief for a painful disturbance in the foot. It shows emphatically the absolute necessity for a complete physical checkup in all cases presenting painful foot disturbances.

Case VII.—H. B., male, aged thirteen, weight 143 pounds, schoolboy. On April 29, 1933 this boy was brought in by his father because of a painful swelling on the dorsum of the left foot over the second and third metatarsal

bones. The condition had appeared gradually and was present for about two weeks. There was no history of injury. Because of a disturbance in the left hip joint this patient had placed no weight upon the left foot for many months prior to December 3, 1932. From December 3, 1932 to April 29, 1933 he had been walking. Examination revealed an overweight boy thirteen years old with a tender swelling over the dorsum of the left foot. x-Ray examination revealed a fracture with callus formation just distal to the middle of the second metatarsal bone. The diagnosis was march foot resulting from overuse of the foot following a long period of inactivity with the contributory factor of excess weight. The treatment consisted of rest off the foot and later exercise and gradual increase in the use of the foot. Complete recovery resulted.

A number of cases of march foot were reported by Speed and Blake in 1933, but in each instance the patient was over twenty years of age. They explained that "The condition has been well recognized for many years, especially by the German and French military surgeons, who frequently encountered it among their troops after strenuous duties or long marches."

CLINIC OF DR. G. K. FENN

ST. LUKE'S HOSPITAL

PAIN SIMULATING THAT PRODUCED BY CORONARY DISEASE

IN collecting material to show causes for pain apart from coronary disease, one is astounded by the multiplicity of causes that present themselves. In many instances the pain is the result of a disturbance of the coronary circulation, but without coronary disease as such disease is usually considered. The latter causes have no place in this discussion, and I shall present no case records bearing upon them. I feel constrained to mention a few of them, because of their frequent occurrence. Hypotension is often accompanied by an anginal type of distress. As the coronary circulation is largely dependent upon the blood pressure, such distress is not surprising. Hypothyroidism is frequently attended by similar distress, even when the blood pressure is relatively undisturbed. The reason here is not quite so clear, but probably arises from the lowered metabolism. Neurocirculatory asthenia or the effort syndrome may be associated with severe pain, sometimes simulating coronary occlusion. Severe anemia may produce anginal pain. Some years ago anginal pain was a common symptom in pernicious anemia. This distress is doubtless due to anemia of the heart muscle as a part of the general anemia.

There are other causes of pain that have their origin in the heart or coronary circulation, but with these few examples we shall proceed to a consideration of causes that are entirely extracardiac. One of the most common sources of confusion in this regard is the pain arising from osteo-arthritis of the spine. Scarcely a week goes by that one is not confronted with the

necessity of differentiating between this disorder and angina pectoris. This arthritic pain may be referred over a large area of the chest, and to the shoulder, and greatly resemble anginal pain. It comes on as a result of exercise, occurs usually in patients past middle life, both of which add to the similarity. Suspicion will be aroused, however, by the fact that the pain is more constant than anginal pain. The pain is accentuated by exercise involving the upper extremity and is accentuated by standing or lying in certain positions, while it is relieved by assuming other and often more uncomfortable positions. These observations will point to the true source. Examination will show a relatively normal cardiovascular system, and usually evidence of arthritis elsewhere. An x-ray of the spine will show pathology in that region.

Case I.—A woman of sixty-eight years gives a history of pain in the left chest and shoulder. This has been present intermittently for six years. She notes the pain is worse for several days after exercise such as housecleaning. There are times when the pain is absent for weeks, but when it reappears it is constantly present in varying intensity for days at a time. Sleeping on the left side seems to aggravate the pain, but sleeping or lying in bed on the back with the left arm extended above the head gives relief. This patient has been told she has angina pectoris, and has been receiving treatment. Examination shows cardiovascular system that is relatively normal for the age. There is a bit more than ordinary of arteriosclerosis. Exercise, such as walking up a stairway, brings no immediate increase in pain. There is evidence of considerable bony enlargement in the fingers and toes. An x-ray of the spine shows spicules and bridging of the dorsal vertebrae. Salicylates temporarily relieve the pain. Three years later the pain is unchanged or slightly better, and the patient has recently successfully combated a bronchopneumonia, a fair accomplishment for a patient of seventy-one years and a fair argument for a pretty sound cardiovascular system.

Acute fibrinous pericarditis with its attendant pain, shock, fever and leukocytosis and elevation of the pulse rate, may easily be mistaken for coronary disease.

Case II.—A young woman of twenty-six had been subjected to an abdominal cesarean section because of an acute toxemia of pregnancy. There was an immediate relief of the toxemia and seventeen days following the operation the patient was enjoying excellent health. On this day she was seized with a sudden severe pain in the precordial region. The pulse rose rapidly to 130, the patient became pale and slightly cyanotic. The temperature rose to

02° F., and the following day there was a marked leukocytosis. No friction rub was heard. The picture closely fitted that of a coronary occlusion, except for one symptom. There was rather severe pain along the left trapezius ridge. This did not rule out coronary pathology, but it raised a strong suspicion of pericardial or pleuropericardial inflammation. On the following day there was a considerable increase in cardiac dullness, with signs of pericardial effusion. x-Ray confirmed the heart size and a diagnosis of pericarditis was justified. The patient made an uneventful recovery.

Pulmonary embolism when not immediately fatal produces a train of symptoms strikingly similar to those of coronary occlusion.

Case III.—A woman of thirty-two, who had rheumatic carditis with mitral stenosis since childhood, came in because of tachycardia and weight loss. In addition there was great fatigue and occasionally a slight elevation of temperature. She was married and had gone through two pregnancies without incident. A subacute bacterial endocarditis was suspected, but the suspicion could not be confirmed. The patient continued to grow worse and a short time later it was discovered that she was again pregnant. A therapeutic abortion was decided upon and she was hospitalized for this procedure. At three o'clock in the morning of the day set for operation she had a sudden excruciating pain in the left chest. This was accompanied by an extremely rapid pulse, 160 to 180, marked dyspnea, pallor and cyanosis. She was extremely apprehensive and was quite convinced that she was dying, a symptom so common in coronary disorders. A diagnosis of coronary embolism was made, assuming that there was present the endocarditis which had been suspected. A pulmonary embolism was considered, but we lacked a good source for the embolus unless we assumed a right heart endocarditis. A few hours following the onset the patient spat up blood. This would fit into either picture. The pain persisted for several hours, and on the following morning a definite area of consolidation was made out in the left upper lobe posteriorly. This was most confusing until about thirty hours after the onset she began to bleed from the uterus. We were now furnished with the source of the pulmonary embolus which the condition proved to be. She aborted spontaneously, and had as a further complication a thrombophlebitis of the left leg, but made a good recovery.

There is a certain variety of pain associated with mediastinitis that occurs uncommonly but is very striking when encountered. I have seen but three cases of such pain. This phenomenon occurs in connection with mediastinal adhesions about the base of the heart. In my own cases it has been associated with adherent pericardium of rheumatic origin. The x-ray shows a partial obliteration of the upper part of

the mediastinal cavity. My cases have all occurred in individuals under twenty-five years of age. The pain is sudden in onset, very severe, and is located beneath the sternum. It has a typical anginal radiation and is associated with dyspnea and pallor. I have not seen cyanosis. The attacks of pain are paroxysmal in character and are rather evanescent and seldom last more than ten to twenty minutes. The patient is rather prostrated following the attack, but is relatively free from pain. They seem most likely to occur at night. In two of these three patients the attacks became progressively more infrequent and finally disappeared. I do not know the outcome of the third case. I have been told that similar attacks of pain occur in certain instances of high-grade mitral stenosis with great dilatation of the left auricle, but I have not encountered such patients.

Spontaneous pneumothorax with sudden onset will occasionally offer a diagnostic problem. This accident is commonly attended by severe pain along the costal border on the side in which the rupture occurs. In left-side pneumothorax it may resemble the pain of coronary occlusion. The acute pain is frequently succeeded by a sense of oppression that adds to the confusion. The onset of the pain is followed by a sudden acceleration of the pulse, a fall in the blood pressure, pallor, cyanosis and symptoms of shock. Dyspnea may be most severe. Examination of the chest will ordinarily reveal the cause of the difficulty. Pneumothorax with insidious onset may show no distinctive findings for several days. With sudden onset the classical hyperresonant or tympanitic chest may not be found. Air in the pleural cavity under certain degrees of pressure will produce a high-pitched tympanitic note that resembles dulness. The ruptured side, however, will be found fairly well fixed. The breath sounds will be impaired, and the heart dulness will be obscured or pushed to the opposite side. The x-ray will substantiate the diagnosis.

It would seem difficult to confuse traumatic pain with that of cardiac origin, and yet we have in our records a case of a physician who came in with his own diagnosis of angina

pectoris or coronary occlusion. He had a steady pain in the left chest. This pain had persisted for almost two days. It was present when he awoke one morning and became worse on exercise. This increase in pain on exercise was a constant feature. There was no shock or disturbance of cardiac rate or rhythm, but he became nauseated as the pain increased. Examination showed a sound cardiovascular system, but a great deal of tenderness over a limited area in the left chest. The x-ray revealed a fractured rib. It was impossible to determine how or when the accident occurred.

Fibrinous pleurisy not infrequently has as its initial symptom sudden, severe pain. This pain may originate in the chest or it may be first felt in shoulder or neck, depending upon the site of the inflammatory process. There appears to be dyspnea, but in reality the breathing is shallow and rapid rather than difficult. While the steady boring pain may resemble that of a coronary attack, the lancinating pain occasioned by a deep breath, will direct attention toward a fibrinous pleurisy and a friction rub will usually be heard if sought for at frequent intervals.

In a similar manner does lobar pneumonia occasionally introduce itself, with a steady boring chest pain of sudden onset. This together with the rusty sputum and the increased respiratory rate often raises a suspicion of coronary disease. The acute infectious nature of the disorder is usually recognized within the first twenty-four hours, and in the majority of cases unmistakable physical signs of pneumonia will appear by the end of the first day. This latter statement is by no means always true. We have numerous records in which the entire pneumonia showed a minimum of physical signs, and the x-ray findings were responsible for the diagnosis.

It would seem almost unnecessary to mention the pain of luetic aortitis and aneurysm in this connection, yet these conditions have been confused with angina pectoris and coronary disease. A careful physical examination will serve to differentiate.

So far I have presented records of pathology in and about

the chest as a cause of anginal pain. I have a few more illustrations of pathology outside the chest that has produced this picture. In a small percentage of peptic ulcers the first indication of their presence will be a perforation into the peritoneal cavity. This accident may be mistaken for a number of things, among which is coronary occlusion. The sudden onset of excruciating pain high in the epigastrium and radiating upward, the profound shock and the elevation of the pulse rate often justify this suspicion. Subsequent developments when sought for will correct the error.

Case IV.—A man of forty-two years, who had an old rheumatic carditis, was suddenly seized with excruciating pain high in the epigastrium. The pain radiated upward into the chest and into the right shoulder. When first seen he was in a state of shock, was pale and prostrated, and the pulse was 120 and thready. Blood pressure had fallen from 130 to 90 mm. Pain was severe and continuous. Respirations were shallow and rapid. There was a suspicious rigidity of the abdominal muscles but not enough to prevent a diagnosis of probable coronary occlusion. Four hours following the onset of the pain the abdominal rigidity had become unmistakable, and in six hours it was sufficient to change the diagnosis. By this time the pain had begun to move downward into the abdomen. The temperature did not rise above 100.5° F., and the highest preoperative white count was 11,000. Seven hours after the initial attack the abdomen was opened and a perforated ulcer was found. The patient made an uneventful recovery. This patient had been under observation for several months preceding the perforation and the presence of ulcer was not suspected.

Another patient that caused a few uneasy days was a man who was hospitalized because of an accident. There was no previous history of heart disease, but while lying in bed he developed an annoying pain in the left chest and shoulder. Realizing the frequent occurrence of thrombosis in patients who are bedridden, the question of a coronary thrombosis was immediately raised. Probably because of the frequent examinations of the cardiac area, the patient became "heart conscious," a condition which had not existed before. Nothing was found to substantiate the diagnosis of coronary thrombosis, and the condition subsequently proved to be a subdeltoid bursitis.

Latterly, we are likely to look upon the diagnosis of "acute

indigestion" with some suspicion. It is true that many, perhaps most, deaths from "acute indigestion" are coronary accidents, but we must not overlook the fact that minor disturbances of the gastro-intestinal tract may produce symptoms closely resembling coronary disease. The most severe abdominal pain may result from the distention of the spastic colon. Gas imprisoned in the splenic flexure will produce pain radiating upward into the chest and in addition will produce dyspnea, pallor and elevation of the pulse. To add to the difficulty of differentiation it must be remembered that in the anginous patient, gaseous distention is capable of producing the attack of angina pectoris. In such situations one is confronted with a delicate diagnostic problem.

Finally, diaphragmatic hernia has been a source of anginal pain. In those cases with which I am familiar the hernia has been situated at the esophageal ring. The x-ray has confirmed the diagnosis. In the cases of Drs. Portis and Bettman surgical repair of the hernia has abolished the anginal symptoms.

This list, I believe, represents the most important situations in which coronary disease may be justly suspected. I would call your attention to the fact that there are pitfalls for you on both sides of the diagnostic fence. Treating a coronary occlusion as an acute fibrinous pericarditis and allowing full liberty with the subsiding symptoms would be likely to result badly for the patient. On the other hand, treating a perforated ulcer as a coronary occlusion would almost certainly result fatally. A correct differential diagnosis is a most comforting thing.

CLINIC OF DR. N. C. GILBERT

ST. LUKE'S HOSPITAL

TREATMENT OF ANGINA PECTORIS

BEFORE discussing the treatment of angina pectoris it will simplify the problem if we first make clear just the clinical syndrome we are referring to when we speak of angina pectoris, and if we review briefly some of the conditions predisposing to the attacks of anginal pain which have a direct bearing upon the treatment. We must also make certain that angina pectoris is clearly differentiated from coronary thrombosis. Just as in coronary thrombosis, the outstanding symptom is pain and pain which differs in no way from the pain of coronary thrombosis, except as to its duration. As in coronary thrombosis, also the pain is due to a blood supply to the heart muscle which is inadequate for its needs.

In coronary thrombosis there is an actual occlusion of one of the coronary arteries by a thrombus within its lumen. There results an interference with the blood supply to some portion of the heart muscle which persists. The extent of the area involved and the amount of anatomical damage and its permanence depend upon the position of the thrombus in the arterial tree and upon the ability of anastomoses, collateral circulation and the thebesian circulation to provide some degree of blood supply in the muscle affected. The amount of damage done may be only slight in some few favored cases, but it is usually enough to produce continued subjective symptoms and to impair the function of the heart to the extent that there are objective evidences of cardiac insufficiency. In some cases the amount of damage done is such as to be im-

mediately incompatible with life or to produce a fatal result in a very short time.

In angina pectoris the attack of pain is not due to the anatomical occlusion of any particular vessel immediately preceding the attack. The adequacy of the coronary circulation in the hearts involved varies through a wide range, but it is not permanently altered to any appreciable degree by any one attack. Whatever the condition of the coronary circulation may be, the pain occurs when the metabolic needs of the heart muscle are increased out of proportion to the blood supply available at the moment. The attack is of short duration and ceases when the demands upon the heart muscle are decreased, or when the blood supply is adjusted to meet the demands. Between the short attacks the patient is in what is a normal condition for the individual.

There are not any characteristic objective findings. It is probable that repeated short attacks may in time result in permanent myocardial damage. It is also probable that an attack may persist long enough to result in ventricular fibrillation and death.

There is a zone of common ground of indefinite breadth where it is difficult to differentiate between the two conditions in the first attack or in some individual later attacks. A coronary thrombosis may occur with very slight or moderate pain, or pain of very short duration with very little in the way of objective findings and still have even fatal consequences. The final outcome of recurring attacks of angina pectoris is very likely to be a coronary thrombosis and such a coronary thrombosis must be kept in mind in observing the recurrent attacks. In any case of doubt, the prudent procedure is to treat the case as one of coronary thrombosis until it has been proved otherwise.

Aneurysm, or a syphilitic aortitis without aneurysm, may be productive of substernal pain and should be differentiated. As a rule, the pain is quite different and whether only a dull ache or a very severe pain, is more prolonged and is not a paroxysmal attack precipitated by some definite cause. An-

ginal attacks may co-exist, especially if an aortic insufficiency is present. Other mediastinal conditions, as tumor or mediastinitis, may cause substernal pain. When such known pathological changes are present, the diagnosis should be that of the condition present, and treatment should be that which considers that condition.

Attacks of angina pectoris usually occur under conditions which entail additional work for the heart muscle. Exertion is the outstanding exciting cause. The amount of exertion is not constant for the individual and will vary in the presence of various physiological and psychological conditions. Attacks are most frequent after meals because of the increase in cardiac output at that time or this increase plus that produced by exertion or emotional excitement. Heavy or indigestible meals predispose to attacks.

The attack may follow any meal or it may be especially after breakfast in the morning when the blood pressure is lower, or after dinner at night when the heavier meal or the fatigue after a busy day may be an additional factor.

The attacks in some cases may come on only during the night and awaken the patient from a quiet sleep. Such attacks usually occur in the early morning hours when the blood pressure reaches its lowest level for the twenty-four hours.

In some patients the attacks may come on without apparent cause when the patient is resting quietly, but usually some relation to some exciting factor may be found.

A large nervous element in the precipitation of attacks has attracted attention since the time of Heberden, who classified angina pectoris with "the incubus, convulsive asthma, numbness, hypochondriac languors, and other ills justly attributed to the disturbed function of the nerves." In support of this he cited the "sudden manner of its coming on and going off, the long intervals of perfect ease," the "influence of passionate affections of the mind," and the number of years it will continue without otherwise "disordering the health."

The present-day observer cannot fail to be impressed, as Heberden was, with the importance of these causes of ner-

vous origin. His nomenclature may be different and he now recognizes that the factor of nervous or emotional origin produces its effects by means of physiological processes which increase the work which the heart must do in proportion to its blood supply or decrease the blood supply while the work which the heart is doing remains constant. Nevertheless, the importance of these causes remains.

Any of the emotions or mental excitement of any nature may precipitate an attack. Anger is a frequent cause. A patient may have frequent attacks on a day when the worry and strain of business life is increased, and few or none on a day when all is going well. Angina pectoris has frequently appeared in those previously free from attacks because of anxiety or of grief or worry over business reverses. Attacks may appear under emotional strain and disappear when the strain is removed. The same man who has daily attacks when he has the responsibility of an executive position to worry over may go on a vacation which calls for much more physical exertion than does his daily life at work and not have a single attack. Or the man who cannot walk from the station to his office without having to stop because of anginal pain, can play golf in comfort.

In these cases which show recurring attacks of anginal pain, the heart shows varying degrees of pathological change from a very great deal to those which are very slight or those which would be expected at the age. Between these two extremes is every possible gradation. In a portion of the cases the symptoms can very definitely be ascribed to pathological changes and in another part of the cases it is very difficult to ascribe the symptoms to pathological changes alone and some physiological factors must be considered. In a very small proportion of cases qualitative changes in the blood are a cause of anginal pain.

In part of the cases there are arteriosclerotic changes in the coronary arteries sufficient to interfere with the blood supply to the heart muscle. The blood supply may be sufficient for ordinary needs in the presence of these changes, or

for the needs of the heart muscle when the body is at rest. But when the heart muscle is called upon to do additional work, as during exertion or during nervous or emotional stress, or during the increased cardiac output occurring during digestion, the arteriosclerotic blood vessels are unable to meet the increased demands of the heart muscle for blood, and pain results. It is in such cases, also, with advanced vascular degeneration that attacks may come on during the night, in the early morning hours, during sleep, when the blood pressure is lowest.

Since the coronary flow is proportionate to the blood pressure, the higher blood pressure present during the day is able to maintain an adequate flow in spite of the vascular changes which are present. When the blood pressure falls during the night, the coronary flow, decreasing with the decreased blood pressure, becomes inadequate to compensate for the vascular changes. In those cases where attacks come on mostly in the morning, the lower blood pressure of the early morning is also a factor. The coronary flow is adequate when the patient is at rest, but not for the additional demands of exertion or those occurring during the digestion of breakfast.

In cases where there are vascular pathologic changes present in the coronaries not sufficient to cause symptoms under ordinary circumstances, a toxic thyroid, by its increased demands upon the work of the heart, may be the determining factor in producing attacks of angina pectoris. The increased emotional instability produced by this condition affords an additional factor.

Aortic insufficiency also furnishes an anatomical basis for anginal pain in some cases. The coronary flow varies with the blood pressure, but especially with the diastolic pressure. In aortic insufficiency, the low diastolic pressure may be such as to decrease the coronary flow to a point where it is insufficient for the work being done by the heart or insufficient in the presence of sclerosed arteries. The low diastolic flow is compensated for in part in most cases by an increased systolic pressure and to some extent by an increased heart

rate. These points must be kept in mind when treatment is planned.

Aortic stenosis is frequently accompanied by attacks of anginal pain. There is usually some degree of insufficiency present which in this case cannot be compensated for by a high systolic pressure or an increased pulse rate. In addition there is the increased work demanded of the hypertrophied left ventricle by the stenosis.

Old healed infarcts from a coronary thrombosis in which an adequate circulation has not been restored by anastomosis or collateral circulation may be the basis for recurring attacks or angina in some cases. In part of these cases we have a history of an initial attack of coronary thrombosis and in others a healed infarct may be found at autopsy which cannot be placed in the history.

Another anatomical basis for a decreased coronary flow is the partial occlusion of the mouth of one of the coronary arteries by changes in the aorta, especially changes due to syphilis. In a few cases there are congenital anomalies of the coronary arteries which may afford an adequate flow in early life, but a flow which becomes inadequate in the presence of the vascular changes which occur later in life.

It would appear certain that anatomical changes in the heart or its vessels constitute the chief basis of anginal attacks and play a part of varying importance in most of the cases. But such anatomical changes cannot be the sole factor. We still have to explain the attacks occurring in cases whose hearts are normal for their age. It is difficult also to explain the influence of the nervous and emotional background upon increased circulatory demands alone. Anatomical changes in the arteries do not explain why a man who has several attacks a day while at work has none upon a vacation where he is more active, but free from responsibility and worry, and why the attacks recur when he again returns to work. Certainly the vascular pathology does not change back and forth. There must be some other factor present. We cannot take the time to discuss this fully here, but it would seem to be connected

with an over-labile autonomic system. It is possible that it is a question of a generalized instability of the vasomotor system and an over-response to normal stimuli which throws an increased load upon the heart. It is possible also that a reflex vasoconstriction of the coronaries is responsible for the attacks in some cases or an increased tonus of the coronaries with inhibition or failure of the vasodilator response. Such a mechanism would not be normal and would not be to the biological advantage of the organism. The organism, however, is not living under conditions of life which are of biological advantage or it may not be a normal organism. The bronchoconstriction of asthma is not advantageous to the organism, but it does occur. In our animal ancestors one might feel that an autonomic system with a lowered threshold to stimuli and an over-response might have been of advantage under conditions of fatigue, but not with a response which involved a vasoconstriction of the coronaries. Such conditions, however, must involve the autonomic system as a whole and cannot be selective of any one function.

Whatever the mechanism, whether active changes in coronary caliber or some response which throws an increased load upon the heart, its association with an overlabile and over-active autonomic system would explain a great deal. It would help to explain the more frequent occurrence in the tense, nervous type of individual who has what Dr. Stuart Roberts very aptly terms the "spasmogenic aptitude." It would explain the more frequent occurrence of angina in business and professional men working under strain, and the effect of overwork, worry and fatigue with inadequate leisure, and inadequate or tiring vacations, for the autonomic system becomes more unstable with fatigue and with chronic fatigue or "staleness." It would explain the occurrence of anginal pain in the so-called "effort syndrome" for whatever that symptom complex is or is not, there is present a lowered threshold to autonomic stimuli and an over-response to those stimuli. It would explain the increased incidence of angina pectoris with

our changed social conditions, with lives of increased strain, and less real rest and relaxation.

Just how much of a factor tobacco is in producing attacks is uncertain. On the whole it probably has little influence. There are some cases which are associated with what is for the individual an overuse of tobacco. Smoking does have a vasoconstrictor effect upon the peripheral vessels and in experimental animals even very small doses of nicotine have a vasoconstrictor action upon the coronaries.

Digitalis administration is responsible for anginal pain under certain conditions in patients with a normal rhythm, and more rarely where more than the optimum dosage is given in auricular fibrillation. A decreased coronary flow has been observed when digitalis is administered to experimental animals. There are other variables determining the coronary flow volume, and while a decrease is observed more frequently than not, it does not always occur. It is assumed to be due to a coronary vasoconstrictor action of the digitalis. Increase in tonus of the heart muscle is probably not responsible for the decreased flow as the flow remains constant under changes in tonus produced in other ways.

In addition to a blood supply to the heart, which is quantitatively inadequate for the needs of the heart muscle, we find some cases where the attacks are consequent upon a blood supply that is qualitatively inadequate, or qualitatively inadequate in the presence of some degree of arteriosclerosis in the coronary vessels.

One such qualitative factor is the decreased oxygen carrying power of the blood in pernicious anemia. In the cases reported by Herrick, who first called our attention to anginal pain in pernicious anemia, arteriosclerotic changes were also present in the coronary arteries. The coronary changes are such as to allow an adequate supply of oxygen with blood of normal oxygen carrying power, but do not admit of sufficient oxygen in the presence of the impaired coronary circulation.

It is not only a question of sufficient oxygen supply. The heart muscle needs other materials carried by the blood, and

sugar is of especial importance. Cardiac pain due to hypoglycemia following the use of insulin has been discussed by several writers in recent years. Strouse and his associates have called our attention to anginal pain with a low blood sugar, following an inadequate carbohydrate diet. Sippe recently reported 4 such cases with a low blood sugar on their normal diet. Relief followed upon glucose given by mouth. Sippe also reported a case with a normal blood sugar, but a ketosis. Improvement followed upon an antiketogenic diet.

Anginal pain may also occur in cases with an abnormally high blood sugar but in whom a deficient insulin supply does not admit of its proper utilization. Such cases are relieved by the proper dosage of insulin.

While I have spent some time in going over the conditions which may constitute the basis for the recurring attacks of anginal pain, I have really gone over the ground much more hastily than I could wish. It is obvious that treatment is not the simple matter of prescribing some one remedy. Just what we are to do to help our patient will depend most of all upon a proper evaluation of the points which we have just considered as well as many other points which we have been forced to omit for lack of time.

The first requisite is that the physician himself should recognize that there is always something which he can do to help and that very often he can do a great deal. He cannot do it by writing out a routine prescription. The physician must obtain personally a careful history and be guided by what he learns from the history in each individual case. There can be no routine procedure. He must give time and thought and understanding and patience. No amount of careful "work-up" can replace the thoughtful understanding of one man who is in a position of leisurely and friendly contact with the patient and who is ready to assume responsibility for the future welfare of the patient.

A great deal of the patient's future depends upon what the physician says. A few years ago Rudyard Kipling in

addressing a medical audience spoke of the therapeutic value of words. And they have a great therapeutic value. In angina pectoris it is especially important just what you say to the patient and how you say it. There can be no fixed rule for this. Second only to the physician's knowledge of the science of medicine—in some cases even more important—is his ability to understand others, to appreciate what is going on in the patient's mind, to feel as he feels and to think as he thinks and to foresee the reaction to the spoken word. The physician must be able to "se fourrer dans la peau d'autrui"—to put himself into the other's skin. No matter what his anatomical background, the nervous element is always present in some degree and has as great an influence upon the patient's future welfare as it has had upon the genesis of his complaint. He must be given faith and confidence and encouragement, and at the same time be told enough so that he can best avoid attacks and prolong life. This is not an easy task.

It is rarely advisable to deny flatly to a patient that the pain of which he complains is anginal. There are some patients with whom such a flat denial is the wiser course and who are quite willing to assume that the pain is that of indigestion or of gas. If they will continue to think so, it is quite as well that they should, provided that the régime ordered by the physician is that which the actual condition requires and that they are kept under observation. But a great many of those who seek advice have had the doubtful advantage of our present-day popular education in medical matters. Daily perusals of health columns and other sources of information have already given them some idea as to what the basis may be. It is better to say what the pain is and to explain the condition in a way which gives them more confidence than to lose their confidence by a flat denial. It is better to tell them the truth and to have them know it, than to tell them a lie and to have them know it. It is better to discuss the condition frankly and to help them to help themselves, than to tell them that they are certainly never better.

the patient's sake and also because you yourself do not always know sufficient in regard to the prognosis. Many a patient given a hopeless prognosis has been made infinitely worse by it and also many a patient given a hopeless prognosis is alive and well years afterward.

There will be a group of patients in whom there are symptoms other than the anginal pain, such as shortness of breath, dyspnea on exertion, and other subjective and objective evidences of impaired cardiac function. Part of this group will consist of those who have previously had a coronary thrombosis or in whom there is myocardial damage due to advanced coronary disease or other factors. Some of them may show very little in the way of objective findings and others will show definite findings of heart disease with or without congestive failure. Included in the group will be cases which show the resultant changes of rheumatic fever, of syphilis, or of renal disease. Here also will belong part of the cases of aortic insufficiency of either rheumatic or syphilitic origin. In all such cases, treatment must consider the pathological conditions present, their etiology, and just how they are interfering with normal physiological processes and functions. In a large part of this group, rest will be the first therapeutic indication, or at least some limitation of activity. It must be determined whether the infective process or other agent, as toxic thyroid, which caused the damage, is still active. If infection is still present or a toxic thyroid is active, that must be considered first of all.

In cases of syphilitic origin, it is best to proceed with considerable caution as regards treatment of the syphilis, and it is sometimes more prudent not to treat the syphilis at all. It is wise to bear in mind Dr. Hay's dictum and "treat the heart first, and not the syphilis." We will discuss this further when we are showing the cases.

There will be a large group of patients in whom the only subjective symptoms are the anginal attacks and in whom there are no characteristic objective findings. A part of this group may be found in perfect health aside from the anginal

attacks. In another there may be some slight evidence of impairment of cardiac function. In a portion of these patients some degree of rest may be advisable at the start. In some this may consist of complete bed rest with a gradual resumption of activity. This will have two objectives, to hasten recovery from fatigue and to permit possible recovery processes in the heart. In some a continued limitation of activity will be advisable. Just what to do in regard to rest is a matter of judgment in each case. There will be some cases where the apprehension caused by such measures will more than offset any possible good results.

Unless there are definite indications to the contrary, most patients are better if allowed to go about their duties and recreations about as usual with only moderate limitations. It is better from a psychological standpoint and there is the possibility also that with a moderate load put upon the heart, further anastomoses and collateral circulation may develop. In many cases the possible fall in blood pressure with prolonged rest is not to be desired. There are obviously patients who cannot be allowed to continue their duties, such as those whose duties would tend to precipitate attacks and those whose sudden incapacity would endanger themselves or others.

There is a great deal in the way of general directions for the patient which should be talked over with him in a quiet, friendly, unhurried and undisturbed visit. The possible exciting causes for attacks, and especially those applicable in his case, should be explained to him. As far as possible he should be instructed to avoid attacks, and to keep within the limits of the exertion which will bring on an attack. If an attack does come on, he should be instructed to stop and rest until it wears off. Unless the pain stops at once with the cessation of effort, he should take a nitroglycerin tablet. There is always the possibility that some recurring attack may be a coronary thrombosis. Because of this it is better that he should be advised that in the event of an attack which is more severe or which bears with it unusual symptoms, he should

return to his home at once in a manner entailing as little effort as possible, and advise his physician.

He should be instructed in regard to the necessity of leading a quiet, calm and orderly existence, avoiding strain and hurry and anxiety. He will find that he can cultivate a spirit of philosophic calm much more easily than he supposes. Shorter hours of work and more rest are always advisable. Recreation should be such as to afford rest and relaxation and such as does not add to the nervous strain. When possible a quiet, restful vacation is always a good start on the treatment and is a therapeutic measure which should be frequently repeated. Frequent quiet week-ends in some small-town hotel where he is not known and where he is out of reach of his business associates afford a very good rest. A short train ride to the hotel provides a sense of detachment from the worries of his daily life. He can take some books and loaf about his room, going to bed early and sleeping until he wakes up in the morning. The motor car is best left at home on the week-end rests and on vacations as well. It is much better to sit back in a comfortable Pullman seat and relax than to be under the constant tension of driving.

Rest before and after meals is an important part of the regimen. After breakfast he should rest before starting out on his daily duties. At noon he should rest before his lunch and after lunch as well. In the evening the patient should get home in time to become thoroughly rested before dinner and should rest after dinner for an hour or more. Fatigue interferes with digestion in adults as well as in children. After meals, during the period of digestion, the heart and circulatory system already have an additional load.

The diet should be adapted to the needs of the individual patient. It should be such as to be readily digestible and one which cannot cause gas. Full, heavy meals are to be avoided. In some patients hydrochloric acid with the meals is indicated and may help in preventing attacks.

There is no indication for any restriction of diet and certainly there is no need for restricting the protein intake, as is

occasionally done. It should not be below the daily protein needs. In the overobese an appropriate diet should be ordered. It is better if the diet is adjusted to the point so that it just about equals the patient's caloric needs. In some cases it may be better to prescribe small meals with the addition of something between meals, if necessary. The diet should afford a carbohydrate ratio sufficient to maintain the blood sugar at the higher limits of normal. If diabetes is present, it should be controlled without insulin in those cases where it is possible to do so and still maintain an adequate diet. In the cases where insulin is necessary, as it frequently is, the patient must adhere to a known and prescribed diet and to a prescribed insulin dosage. The insulin always should be such as to maintain the blood sugar at a level at which hypoglycemia can be certainly avoided. It is better to allow a trace of sugar to show in the urine.

Occasionally attacks of angina pectoris occur in those who are suffering from symptoms of duodenal ulcer. Some of these patients have an active ulcer with deformity of the bulb. Others do not show an actual deformity but show evidence of an overirritable bulb with frequently no ulcer. Such patients should be put under ulcer management and especially ulcer management associated with the use of some mild sedative as phenobarbital. In many of these cases the symptoms are only another expression of Dr. Roberts' "spasmogenic aptitude."

Many angina patients have a constipation of the spastic type. This should be controlled as far as possible by diet. A glass or two of hot water on arising may help. If necessary, liquid or solid vaseline or one of the preparations of vaseline which do not contain a cathartic can be used. Solid white vaseline is especially valuable. It is not hard to take. A large ball of it can be placed on the back of the tongue and swallowed night and morning. If the diet does not afford sufficient bulk, agar can be added.

If cathartics are necessary, the milder saline laxatives are

preferable. Strong or stimulating cathartics may predispose to attacks, especially in those patients with spastic colons.

The question of the use of liquor frequently arises. Some patients are unquestionably the better for its moderate use, especially the more elderly patients. Others with even a very moderate or small amount may have gastric disturbance which predisposes to an attack. Liquor is best avoided as a general rule.

Just what to decide in regard to the use of tobacco must be decided according to the individual patient. Its use should certainly be moderate and it should not be used on an empty stomach. If there is any question as to its harmful effects, it should be omitted.

Such general directions as have been indicated above are quite as important as any part of treatment. A little pocket booklet with some very sensible and wise general directions for the patient's use has been prepared by Dr. John Sproull of Haverhill, Massachusetts, and is a very good guide for the patient to have.

When possible, the patient should spend the winter in a warm equable climate. High altitudes are always to be avoided and especially so where there is much actual cardiac pathology. For every increment of elevation, the heart has just so much more work to do. Patients will frequently return from a vacation at a high altitude and inform you that your warnings in that regard were quite unnecessary, but others will return and tell you that they wish that they had obeyed your directions. The same caution applies in regard to trips by plane. Conditions may force the plane to remain at a high altitude for a long period. A trip from Omaha to Chicago at 6000 feet undid the results of months of care in the case of one patient.

The attacks themselves are best relieved by amyl nitrite or nitroglycerin. Amyl nitrite acts a little more promptly but is less convenient and always conspicuous, as well as being a source of annoyance to others. Nitroglycerin dissolved under the tongue acts promptly enough for all clinical pur-

poses. It is especially useful because it can be readily carried in the pocket or handbag and can be used without attracting attention at any time. It loses strength rapidly when exposed or with age; it is best purchased in the small hypodermic tube of 20 tablets and kept tightly stoppered. The usual dose is $\frac{1}{100}$ grain. There are patients who have uncomfortable symptoms or very rarely syncope with this dose and in whom a smaller dose does better. The dose can be repeated if necessary. The other nitrites act too slowly to be of much use, although their action is more prolonged. If the attacks last long enough to demand a drug with more prolonged action, there are more serious aspects which must be considered.

Heberden recommended "spirituous liquors" in the treatment of the attack and they are still valuable. Hot, strong, black coffee is of help in some cases and may act as a substitute when other means are not available.

A large part of the treatment between the attacks consists of the evaluation by the physician of just what it is that predisposes to the attack and precipitates it, and the directions which the physician gives the patient as to his care. There is no remedy which will alter anatomical changes in the arteries and certainly none which will "cure" angina pectoris. Nor is there any one drug which will afford any degree of relief in all cases. But most cases can at least be materially helped by medication.

In our experience here we have obtained better results by the use of the purine base group than with any other one medical treatment. In some few cases almost complete relief has been obtained. In most cases some degree of relief has been obtained, from a very great deal to moderate or slight. As would be expected from the nature of the conditions which cause the pain in angina pectoris, there must be cases where relief cannot be obtained.

It is not possible to say which of the purine base preparations is the most valuable. On some occasions a result will be obtained with one preparation when another has not been

effective, or one will cause uncomfortable symptoms and another not. Of the theobromine preparations, we use most frequently theobromine calcium salicylate (theocalcine), or the alkaloid theobromine, and of the theophylline preparations, theophylline ethylene diamine (aminophylline) or theophylline calcium salicylate (phyllicin).

We make use of most of the other preparations at one time or another, however, partly because of their lower cost and partly because, for no reason which we can assign, occasionally one preparation seems to work better than another.

The alkaloid theobromine we prescribe in 5- and 7.5-grain tablets, and theobromine calcium salicylate (theocalcine) 7.5-grain tablets, one or two at a time. Theobromine sodium salicylate and theobromine sodium acetate we use in 10-grain capsules. The acetate salt carries a little more theobromine than does the salicylate. The dosage of the theophylline preparation is much lower in each case. The alkaloid theophylline is prescribed in 2-grain capsules, and the theophylline ethylene diamine (aminophylline) in 1.5-grain tablets, and the theophylline calcium salicylate (phyllicine) in 4-grain tablets.

All of the series have some disadvantage. Most of them may, and occasionally do, cause some unpleasant symptom in the way of nausea, gastric distress, headache, or nervousness. Theobromine calcium salicylate (theocalcine), because of its insolubility in the stomach, rarely causes unpleasant symptoms. The same is true of theophylline ethylene diamine (aminophylline). Theophylline calcium salicylate is equally effective and in some cases more so, and is usually well tolerated. All are best taken during the meal; a little food, then the drug and then the rest of the meal.

In experimental animals the theobromine preparations cause the greatest increase in coronary flow. The theophylline preparations are next, and caffeine the least effective. Theophylline ethylene diamine is quite as effective as a vasodilator of the coronaries as the theobromines because of the

vasodilator effect of ethylene diamine. The theophylline calcium salicylate is quite as effective clinically in our experience.

It is probable that some degree of tolerance is acquired of these drugs and Meyer has shown that not only tolerance is acquired, but a cross tolerance is acquired as well to others of the series. We have assumed that such a tolerance is acquired clinically and have thought on some occasions that we have had evidence of this in some of our patients. In order to avoid acquiring a tolerance, we have been in the habit of using the theobromine preparation one week and a theophylline preparation the alternate week. The effects of this procedure is open to question where cross tolerance is so easily acquired. With the same objective in mind, we have, where possible, used the medication for four days of each week and omitted medication for three days. While a tolerance may be acquired there are certainly a great many patients who do not acquire such a tolerance.

In the second case which we are to show this morning, theobromine preparations have been used steadily for seven years and for the past two years the patient has insisted upon using the alkaloid theobromine because she gets more relief with this preparation. If she omits the medicine, the symptoms return as before.

Another case returned for a check-up this week who has used the theobromine preparations steadily for eleven years and is still benefited.

In order not to discourage the patient by any untoward effects, at the onset, we start with the theobromine calcium salicylate (theocalcin) which only very rarely causes distress, and then alternate with the theophylline ethylene diamine (aminophylline) or the theophylline calcium salicylate (phyllicin). Later we try other preparations and use the preparation and dosage which we find the most effective and the best tolerated.

We think that in these patients who have shown little or no effect at first and then have done exceptionally well, there is an actual improvement in the underlying condition. This

has been the opinion, also, of Dr. F. M. Smith and he has confirmed this by his experimental work on the dog, showing that with the use of the purine base diuretics, there is an actual increase in the anastomoses and collateral circulation consequent upon the constant vasodilation produced by these drugs.

Good results have been reported from the use of various tissue extracts. In experimental animals when administered into the vein, they have been shown to increase the coronary flow, and to dilate the peripheral vessels. In the preparations which we have used, we have observed little or no increase in the coronary flow in the experimental animal.

In peripheral vascular disease the clinical results following the intramuscular injection of tissue extract have been definitely good, although there has been some doubt as to whether this clinical improvement was due to a vasodilatation or not. It is possible that the good results may be due to some factor other than vasodilatation and that they are concerned in some way with muscle metabolism.

In our experience with the use of tissue extracts, which has been relatively small, we have not found them as useful as agents of the purine base series, and we certainly do not feel that they could replace these drugs. In some cases we feel that they have been of very real value, and have caused further relief of symptoms when the purine base drugs were not wholly effective. In such cases we have continued the use of the purine base drugs. On a few occasions the patient has not done as well with their use, and we have considered that a fall in the systemic blood pressure was responsible for the result. Care must be taken not to inject into a vein.

Different nitrite preparations, especially those with a more prolonged action, as erythrol tetranitrite or sodium nitrate, may be used routinely to prevent the recurrence of attacks. In our experience they have been rarely necessary, but there are occasions when they should be given a trial. They should not be used to the point of maintaining a lowered blood pressure and in some cases we think that we have seen untoward

results from their daily and frequent use. The nitrite preparations are occasionally given to a patient in order to undertake some additional effort without an attack. We do not recommend this to our patients and prefer that they do not undertake the additional effort.

Alcohol taken wisely and moderately has a place in the treatment of angina pectoris in certain cases. "Wine and cordials taken at going to bed will prevent or weaken the night fits," wrote Heberden, and it is a method worth trying in some cases. Heberden goes on to state that "nothing does this as effectively as opiates" and they also must be considered today, and especially so when age or a degree of illness is reached when habit forming is not to be feared.

Phenobarbital is of great value, especially when used in conjunction with the purine base drugs, or with other medication. We prefer to use it separately and not combined with theobromine, in order that we may vary the dosage as necessary. We attempt to use a dose which will produce a sedative effect without drowsiness. Sometimes one of the more rapidly acting derivatives is of more value at night.

Potassium iodide is used a great deal as an orthodox method of treatment. I have never been able to persuade myself that I could attribute any favorable results to its use. It certainly will not bring about any anatomical changes in the vessels. But where a drug has been used so consistently for so long a period, one wonders if there is not some possible virtue in it after all.

Digitalis is best not used at all except in the cases where there are definite indications for its use, as auricular fibrillation or a passive congestion which does not yield to other measures. There is no reason in ordinary cases why it should be used, and there are reasons why it should not be. We have obtained definite experimental evidence that digitalis decreases the coronary flow and clinically attacks have been made more severe and more frequent by its use or have been precipitated by its use. Especially should it be avoided where there is an aortic insufficiency. In aortic insufficiency, the coronary flow

is at a great disadvantage because of the low diastolic pressure. In most cases this is compensated for in part by an increase in the systolic pressure and by an increased pulse rate. Digitalis may lower the systolic pressure, may decrease the pulse rate, and possibly further lower the diastolic pressure, each of which factors would tend to cause the coronary flow to become inadequate.

Those cases in which pernicious anemia is a factor influencing the attacks yield to proper treatment. If a hypoglycemia forms the basis for the attacks, diet or glucose by mouth should be sufficient.

Various surgical methods have been devised for the relief or prevention of anginal attacks. An adequate discussion would take more time than we can give here. The operations involving ganglionectomy or sympathectomy are applicable only in a few chosen cases and the results have not been encouraging. Paravertebral injection of alcohol into the first five thoracic ganglia, as advocated by White, is more effective and does not carry the mortality that the more extensive surgical procedures do. More recently Blumgart and his associates have advocated total thyriodectomy in the treatment of angina pectoris. Their results as observed over a period of two or three years have been satisfactory and our own very small series has shown good results; the cases must be chosen with great care and it is not a procedure to be used indiscriminately.

I have postponed showing cases until the last, and we shall be obliged to show them very briefly and give only the essential history and findings.

Case I. This first patient is a white clerk, aged fifty-four, who entered St. Luke's Hospital in September, 1929 with typical attacks of anginal pain. These attacks came on while walking from his home to the elevated railroad and from the train to his work, and again on going home in the evening. He would have 1 or 2 attacks in the 4 blocks which would necessitate his stopping and sitting down. They would wear off in a minute or two and he would proceed. For several months the attacks would appear only once or twice a week, but for two weeks before entrance there were frequent daily attacks.

Physical examination revealed no evidence of cardiac pathology. A 2-meter chest plate showed a heart of normal contour whose transverse diameter was

43 per cent of the transverse diameter of the chest. The great vessels were normal. An electrocardiogram shows the T wave in lead II leading off from very slightly below the iso-electric line. Otherwise it was normal. Blood, blood chemistry, Wassermann and urine were normal. Blood pressure varied around 120 systolic and 80 diastolic.

The patient was discharged on the third day. He was instructed to take theocalcine, 7.5 grains four times a day for one week, and metapbyllin, 1.5 grains, each alternate week. There was no improvement and October 13, 1929 alkaloid theobromine, 7.5 grains, was substituted for the theocalcine, giving about twice the dosage of theobromine. November 11th the pains were some better, and definitely better on December 22nd. February 9th he reported that the attacks were "about gone" and were better in the week when he took the alkaloid theobromine. March 9th he reported that he had had no attacks during the preceding week. There was no pain until October when there was some slight pain, but not what he would call an attack. There was no pain until July 1, 1932 when he had some pain again. On both of these occasions no history of any provocative cause could be elicited. There have been no attacks since that time. Beginning in 1933 the medication has been taken only intermittently for a month or two at a time and a month without medication.

It does not seem probable that there was a coronary thrombosis at the onset. There was no history of an attack, but there was a history of isolated short attacks of anginal pain becoming more frequent. It is not probable that anastomoses and collateral circulation improved spontaneously in so short a time. We have, too, the definite statement that he was better the weeks that he was taking the more effective dose of theobromine, than when on the relatively smaller dose of metapbyllin.

We consider that in this case relief was obtained by the medication and that the long-continued medication and continuous vasodilatation increased the anastomosis and collateral circulation, resulting in the present complete relief from symptoms.

Case II.—This next case represents a very much less favorable type for treatment, but is a case which we are very sure has been benefited by treatment.

The patient is a housewife, aged sixty-two. She entered St. Luke's Hospital on April 18, 1928, complaining of dyspnea upon exertion and edema of the lower extremities which had been present for three years, and of attacks of anginal pain, present for the past two years. The attacks of angina pectoris occurred several times daily, especially after meals. There were also nocturnal attacks.

Except for the obvious evidence of aortic insufficiency, she is a normal appearing woman for her age and was not essentially different at her entrance seven years ago.

At the time of entrance, physical examination revealed a very typical aortic insufficiency with a loud diastolic and a loud systolic murmur over the aorta, and an associated mitral insufficiency. There was nothing in the previous history to indicate the occurrence of rheumatic fever or syphilis. There have been no pregnancies.

A 2-meter chest plate showed a left ventricular hypertrophy, the left border 11.7 cm. to the left, and the right border 3.1 cm. to the right of the mid-sternal line. The transverse diameter of the heart occupied 55 per cent of the transverse diameter of the chest. At the present it occupies 56 per cent of the transverse diameter of the chest. Repeated Wassermann and Kahn tests were negative at this time, and have continued negative. Blood chemistry was normal throughout. Routine blood examinations showed only a moderate secondary anemia. The urine was normal except for a trace of albumin. The electrocardiogram showed evidences of extensive coronary and myocardial changes.

The blood pressure on entrance was 310 systolic and 50 diastolic. It has continued high, and since leaving the hospital has varied from 300 to 198 systolic, and 56 to 44 diastolic. It has averaged high in January and less in July. It apparently bears no relation to the pain.

The patient remained in the hospital for two weeks. During this period of bed rest the evidences of passive congestion disappeared. The attacks of anginal pain were less frequent than when up and about, but the patient still continued to have several attacks daily. On discharge, she returned to the follow-up clinic, where she was placed upon the purine base diuretics at once with immediate improvement. She had less pain when up and about with this medication than when at rest without it. During the intervening seven years she has continued for the most part upon this medication. It has been discontinued several times for periods of two to four weeks. During these periods everything at all reasonable that we have heard of has been tried. Nothing was found which would give her as much relief as her regular treatment. During the last two years she has been upon the alkaloid theobromine and theophyllin ethylene diamine. Attacks still occur, but are less frequent and less severe. There will be periods of one to three weeks when there are no attacks, and at other times there will be 1 or 2 or 3 attacks a week. The last few months there has been less limitation of activity and fewer attacks than at any other time. Moderate shortness of breath still persists, but there is no edema.

During these seven years of observation it is possible that part of the improvement has been due to the increased anastomoses and increased collateral circulation which might have occurred spontaneously with time. The improvement, however, began at once with the administration of the purine base

43 per cent of the transverse diameter of the chest. The great vessels were normal. An electrocardiogram shows the T wave in lead II leading off from very slightly below the iso-electric line. Otherwise it was normal. Blood, blood chemistry, Wassermann and urine were normal. Blood pressure varied around 120 systolic and 80 diastolic.

The patient was discharged on the third day. He was instructed to take theocalcine, 7.5 grains four times a day for one week, and metaphyllin, 1.5 grains, each alternate week. There was no improvement and October 13, 1929 alkaloid theobromine, 7.5 grains, was substituted for the theocalcine, giving about twice the dosage of theobromine. November 11th the pains were some better, and definitely better on December 22nd. February 9th he reported that the attacks were "about gone" and were better in the week when he took the alkaloid theobromine. March 9th he reported that he had had no attacks during the preceding week. There was no pain until October when there was some slight pain, but not what he would call an attack. There was no pain until July 1, 1932 when he had some pain again. On both of these occasions no history of any provocative cause could be elicited. There have been no attacks since that time. Beginning in 1933 the medication has been taken only intermittently for a month or two at a time and a month without medication.

It does not seem probable that there was a coronary thrombosis at the onset. There was no history of an attack, but there was a history of isolated short attacks of anginal pain becoming more frequent. It is not probable that anastomoses and collateral circulation improved spontaneously in so short a time. We have, too, the definite statement that he was better the weeks that he was taking the more effective dose of theobromine, than when on the relatively smaller dose of metaphyllin.

We consider that in this case relief was obtained by the medication and that the long-continued medication and continuous vasodilatation increased the anastomosis and collateral circulation, resulting in the present complete relief from symptoms.

Case II.—This next case represents a very much less favorable type for treatment, but is a case which we are very sure has been benefited by treatment.

The patient is a housewife, aged sixty-two. She entered St. Luke's Hospital on April 18, 1928, complaining of dyspnea upon exertion and edema of the lower extremities which had been present for three years, and of attacks of anginal pain, present for the past two years. The attacks of angina pectoris occurred several times daily, especially after meals. There were also nocturnal attacks.

Except for the obvious evidence of aortic insufficiency, she is a normal appearing woman for her age and was not essentially different at her entrance seven years ago.

At the time of entrance, physical examination revealed a very typical aortic insufficiency with a loud diastolic and a loud systolic murmur over the aorta, and an associated mitral insufficiency. There was nothing in the previous history to indicate the occurrence of rheumatic fever or syphilis. There have been no pregnancies.

A 2-meter chest plate showed a left ventricular hypertrophy, the left border 11.7 cm. to the left, and the right border 3.1 cm. to the right of the mid-sternal line. The transverse diameter of the heart occupied 55 per cent of the transverse diameter of the chest. At the present it occupies 56 per cent of the transverse diameter of the chest. Attacks still occur, but are less frequent and less severe. There will be periods of one to three weeks when there are no attacks, and at other times there will be 1 or 2 or 3 attacks a week. The last few months there has been less limitation of activity and fewer attacks than at any other time. Moderate shortness of breath still persists, but there is no edema.

During these seven years of observation it is possible that part of the improvement has been due to the increased anastomoses and increased collateral circulation which might have occurred spontaneously with time. The improvement, however, began at once with the administration of the purine base

drugs. The symptoms even now recur with greater frequency and severity if the medication is discontinued. She is better also when upon the alkaloid theobromine than when trying the other preparations. We feel that the medication has played a part in producing the increase in the anastomoses and collateral circulation which has probably occurred.

Case III.—This especially healthy appearing man represents an unusually favorable type for thyroidectomy for the relief of anginal pain and has shown especially good results.

The patient is an electrician and the proprietor of a radio sales and repair shop, aged fifty-nine. He came to the out-patient department November 12, 1933, complaining of frequent attacks of anginal pain, loss of weight, and sleeplessness present since the previous June. The attacks of pain occurred frequently during the day on slight exertion, and at night while lying in bed he had as many as 12 attacks. He was unable to work and had been practically bedfast.

There was a very obvious toxic thyroid present, with a metabolic rate of plus 32. The blood pressure was 164 systolic and 90 diastolic with a pulse of 112. Although he improved during his preoperative course of iodine and there was an amelioration of his thyroid symptoms, there was no change in the frequency or the severity of his anginal attacks. Theobromine sodium acetate, 40 grains daily, showed no effect.

He entered the hospital on December 3, 1934 and a subtotal thyroidectomy was done the next day by Dr. S. W. McArthur. After an uneventful post-operative recovery, he was discharged on the eighth day.

He has had no attack at any time since the operation. The night before the operation he had several attacks of pain. Even changing his position or sitting up might bring on an attack. The night following his operation he got out of bed and closed the window and moved a screen without pain. It would seem that there was something else in addition to the lowered metabolic rate which was responsible for the absence of pain after thyroidectomy. It is very improbable that the rate was materially lowered in the few hours intervening between the operation and his undertaking exertion that he could not possibly have undertaken before the operation. On the ninth day after the operation the rate was plus 25.3, later falling to minus 25.6, where it still remained last month.

He regained his weight rapidly, passing his former weight, and returning to his usual weight when he resumed exercise. There have been no attacks between the time of operation and now. When I called him to ask him to come to the hospital, he had just returned from a 2-mile walk on a cold winter evening. There is no shortness of breath. He has even experimented with running.

This case has been, of course, an especially favorable case. The thyroidectomy would have had to be done, irrespective

of the angina pectoris. The case does not belong with the group which has been reported from Boston and which has shown such favorable results.

In showing this second case of thyroidectomy done for the relief of anginal pain, I do not wish to be understood as advocating this line of treatment except in a very few chosen cases. In the other case just shown, his condition quite aside from the angina indicated a thyroidectomy. In this case which we are about to show, every other possibility was exhausted before a thyroidectomy was done. Most cases can be handled medically and we think, as far as we know now, to better advantage. Until cases have been followed for a long period of time and the results watched carefully and impartially, nothing definite can be said as to the advantages of thyroidectomy in chosen cases of angina pectoris. It is obvious that no matter how satisfactory the results may be in some cases, the procedure will never be applicable to more than a well chosen few.

In this second case of thyroidectomy, the operation was only done after months of unsuccessful efforts with other treatment. We were especially hesitant because of the associated pathological conditions.

Case IV.—The patient is a normal appearing man of fifty-three, a real estate salesman. He entered St. Luke's Hospital in September, 1933 because of attacks of angina pectoris. Until two months before entrance the patient was in his usual health. About this time he began to have occasional attacks of anginal pain. These rather rapidly became more frequent and more severe until it became impossible for him to continue at work. Attacks are now precipitated by the slightest exertion so that he is practically bedfast. There are one to several attacks at night. There has been no shortness of breath but there is some mild sub-sternal pain present between the attacks part of the time.

Physical examination showed nothing of great significance. The heart was within normal limits of size. There was a soft systolic murmur at the base, under the sternum, not transmitted. The heart sounds and rhythm were normal. Physical examination at present is quite unchanged except that he has gained weight and has not the nervous, apprehensive appearance which he had at that time.

Laboratory examinations showed the heart to occupy 47.7 per cent of the transverse diameter of the chest, 5.7 cm. to the left and 4.7 cm. to the right of the midline.

The electrocardiogram showed only moderate variation from normal between the attacks, but during the attacks the tracing showed a marked deviation from normal type, indicative of coronary involvement.

The blood pressure was 120 systolic and 74 diastolic on entrance, and has since varied only slightly above and below these levels.

The blood Wassermann and Kahn were strongly positive, and the spinal fluid Wassermann was mildly positive. There was a low paretic curve with the colloidal gold test. The basal metabolism rate was minus 12. Routine blood examination showed a moderate secondary anemia. The urine was normal upon examination and functional tests were normal.

The patient remained in the hospital for seventy-one days, and then was discharged to a convalescent home. During this time he received various theobromine and theophyllin preparations. Neither these drugs nor other attempts at medication showed any definite effect. He improved enough so that he could be up and around the ward, and while he was much better, still had daily attacks and occasionally attacks during the night. There was no improvement that could not be accounted for by bed rest and time.

We feel that in cases of syphilis involving the circulatory system we should be very careful in regard to our antisyphilitic treatment. What we do depends entirely upon the cardiac condition and treatment directed at the syphilis may be omitted altogether until the cardiac condition has improved. We are very certain that we have seen even mild cardiac conditions become rapidly very much worse with vigorous or even mild arsenical therapy. As Dr. William Allen Pusey puts it, "Syphilitic tissue is better than no tissue at all." There are doubtless cases where vigorous arsenical treatment does not show untoward results, but we prefer not to take the risk. We start with mercury or mercury and iodide, and with bismuth in alternate courses, and even watch these closely. If subjective symptoms are aggravated or the pulse rate is increased, we stop for a time.

In this case symptoms became definitely more pronounced with mercury and with mercury and iodides or with bismuth, and all antisyphilitic treatment was discontinued temporarily.

After discharge the patient continued to return to the outpatient department. Mercury or bismuth were again tried at various times for short intervals, but could not be continued steadily. The purine base drugs in one form or another were

continued. He felt that he was better upon the alkaloid theobromine and he received this most of the time.

In June, 1934, he was a little better clinically, but he still had several attacks daily and could not return to his usual occupations. The convalescent home could not keep him longer, and he could not take care of himself alone in a rooming house. It was decided to do a thyroidectomy in spite of the unfavorable outlook. He was accordingly operated upon June 30, 1934, by Dr. H. E. Mock, who did a subtotal thyroidectomy. He made an uneventful recovery and was discharged on the twelfth day. There were no anginal attacks after the operation during his stay in the hospital.

Since his discharge he has been free from his former attacks, except for a few scattered attacks on prolonged effort. He has some mild pain, described as a burning sensation, under the upper third of the sternum on walking. This may come on in two blocks or it may be only after seven or eight blocks and it goes away as soon as he stops.

He is taking the alkaloid theobromine and theophylline calcium salicylate on alternate weeks, as he states that he feels better on these two.

It is interesting that since the thyroidectomy the metabolic rate has been higher than before, and has varied between minus 6 and minus 8.

He is receiving alternate courses of mercury and bismuth in the skin clinic. At first these were discontinued occasionally because of some increase in the substernal pain, but now are going along continuously. Because of the spinal-fluid findings we do not wish to lose any more time than is necessary in our antisiphilitic treatment and will begin to use the arsenicals sooner than we otherwise would.

He is still limited in his activities, but has returned to work and to his normal mode of life. Even with the residual substernal pain, which was to be expected, he is infinitely better off than with the recurring and frequent attacks of angina.

NORTHWESTERN UNIVERSITY MEDICAL SCHOOL

PAIN IN THE ABDOMEN: CLINICAL SIGNIFICANCE AND CONSIDERATION OF RELIEF

PAIN as a symptom of abdominal pathology is deserving of careful study since it is one of the most important single symptoms and often most dramatic to the patient. In consideration of this symptom we must use it in the broadest sense, varying from distress of mild character to that of a severe agonizing colic. This interpretation is obviously necessary since vague distress at times may develop into acute pain and also because it will necessarily vary with the individual reaction. Sensations of pain may be materially altered by the apprehensiveness of the individual. A practical analysis of pain should contemplate its origin and some rationale for its particular characteristics, some understanding of the pathologic physiology involved. One must consider, furthermore, whether the pain is intra-abdominal or extra-abdominal, as the symptoms may be very confusing.

In the interpretation of pain we must of necessity relate it to other associated symptoms. Seldom will it occur that a definite pattern of pain will be adequate in any instance to make a definite diagnosis.

Generally speaking, the walls of the abdominal cavity are innervated by the cerebrospinal nerves, while the viscera are innervated by the splanchnics. The lower surface of the diaphragm is supplied by the phrenic, the afferent nerves having their origin in the fourth cervical segment of the cord. The anterior and lateral walls of the abdomen are supplied by the lower six thoracic and first lumbar nerves. Pains originating in the stomach or other viscera may be referred to the surface

of the body supplied by the corresponding spinal segment. It is obvious, therefore, that diseases of the spinal cord may refer pain from these corresponding root segments which may simulate disease of the several viscera. Gastric and intestinal pains are thought to be due either to increased tension of the muscle wall, to involvement of the peritoneum or both.

Rapid distention of the stomach has been observed to produce pain, the intragastric pressure indicating that the muscular tension was the chief factor involved. The spasm of the pylorus is another example. There is a close relationship between hypersensitivity of the gastric nerves and pain as exhibited in the distress of ulcer of the stomach or duodenum. The absence of pain during observation of the large visible peristaltic waves strong enough to lift the abdominal wall or similarly noted during fluoroscopic study would indicate that the ordinary conception of increased muscular tone was not the prime factor causing the pain.

A peculiar conditioning of nervous reflexes associated with an increased sensitivity of the nerves of the stomach or duodenum accounts best for the pain activated by the acid secretion.

The mucous membrane of the stomach and intestines is relatively insensitive to thermic, tactile and chemical stimuli. When weak acid solution is put in the stomach bearing an active ulcer, pain will be produced and if, as Palmer has shown, the ulcer is quiescent, no pain will result. This would indicate that acid is an essential factor in the production of pain when proper conditioning of nerves occur.

It is more difficult, however, to produce pain in the intestines. Sudden distention of the colon from gas associated with excessive peristalsis or the injection of large quantities of water in the colon while in an irritable state, will often produce marked pain. These observations are essential to bear in mind when opportunity presents itself in test-out in the differential diagnosis between ulcer and disorders in the colon.

The peritoneum covering the stomach and intestine is also relatively insensitive, whereas the parietal peritoneum is very sensitive. It seems quite reasonable, therefore, that tension

on the parietal peritoneum from distention of the viscera produces much the greater part of pain. This is particularly true in perforations, local peritonitis and intestinal obstruction. The cramplike pain of intestinal obstruction seems to be due to the extreme tone initiated by excessive and vigorous peristalsis. When free portions of the intestine are involved, there is a tendency for the pain to be referred to the epigastrium or the neighborhood of the umbilicus, whereas that arising from fixed portions is usually related directly to the region involved. Let us now analyze the pain picture as it is related to various disorders in the abdomen.

A typical colic frequently means a definite pattern of pain or distress. We must also ascertain whether the pain is acute or chronic. An acute pain usually means sudden onset from infection, perforation, obstruction, or some intra-abdominal accident, as vascular occlusion.

Inquire as to associated temperature, shock, nausea, or vomiting. In the chronic recurrent pain picture is there relationship to food ingestion, either of quality or time, and does bowel movement or certain physical activity influence the pain? Whether acute or chronic we must attempt to determine the point of maximum intensity of pain; the direction and point of reference. Is it influenced by any test procedure and with what other symptoms does it occur?

Before discussing the intra-abdominal lesions, let us analyze briefly the pain as it may be referred to the abdomen from extra-abdominal sources.

Diaphragmatic pleurisy or pneumonia of the right lower lobe may produce a referred pain to the upper abdomen or even as low as McBurney's point. If jaundice is an accompanying symptom, as is not infrequently the case in pneumonia, the deception is complete. Only recently we observed a patient who had had a previous x-ray and diagnosis of cholelithiasis, who at the time was suffering from very severe upper right quadrant pain. Two days passed before there were sufficient physical signs in the lower right chest to bear out the diagnosis of pneumonia. The pain in the upper right

quadrant, although severe, was at no time associated with rigidity of the right rectus muscle and the temperature was out of proportion to the abdominal findings. Pneumonia was finally positively diagnosed.

Pulmonary tuberculosis or bronchiectasis may simulate a lesion of the abdomen. Tuberculosis particularly will be confused and rightly so, since it is not infrequent that we find intestinal tuberculosis following the pulmonary involvement, yet the involvement of the diaphragm, with pain referred to the neck through the phrenic nerve and a negative gastro-intestinal study, will make the diagnosis certain of uncomplicated pulmonary tuberculosis.

The abdominal nerves may be affected at their source, as in tabes dorsalis, osteo-arthritis, Pott's disease or osteomyelitis. When the bodies of the vertebrae are involved, it may require no little ingenuity to prove the origin of the pain. Pressure over the involved bone may reveal marked tenderness, as in Pott's disease or osteomyelitis. Bed rest and a body cast may be finally necessary to diagnose correctly the bone involvement.

A coronary accident may so closely simulate an intra-abdominal disorder as to lead to serious consequences. A brief case report of such an experience might be worth analyzing. A man, aged sixty-five years, came to the hospital complaining of severe right upper abdominal pain. He gave a history of similar attacks over a period of several years. As a rule, these attacks were sufficiently severe to require morphine for relief. At no time did this man note pain over the precordium, much less a reference pain into the left shoulder or left arm. He showed no particular evidence of shock; blood pressure was down to 100 systolic. Previous to my examination he had had a Graham-Cole test which failed to visualize the gallbladder. Diagnosis, therefore, of gallbladder disease seemed probable. However, when I was called to see him, it was quite evident that the man was having some distress related to the cardiovascular system. His chief complaint on the morning of my examination was that of dyspnea

and with continued observation it became apparent that the dyspnea was associated with Cheyne-Stokes respiration. The cardiogram was taken at once and revealed marked evidence of myocarditis and disturbance in the conduction time. He succumbed to this coronary accident, and postmortem revealed a large infarct in the myocardium. The gallbladder was normal. Evidences of numerous healed infarcts were found in the myocardium, probably accounting for the previous gallbladder-like colics that he had experienced before.

Experiences of this kind are quite common. Many physicians have noted similar confusion ever since Herrick called our attention to coronary occlusion in 1912, but one is never so impressed by the possibilities of confusion until he has made a number of mistakes. Recently a not dissimilar problem was presented. Acute pain in the abdomen was thought to be due to a perforated duodenal ulcer. The patient gave a history of a duodenal ulcer of many years' standing and had taken rather poor care of himself. Shortly before the onset of this acute attack of pain, he had noted definite recurrence of his ulcer symptoms. He experienced a sudden epigastric pain radiating slightly upward into the chest. This radiation, however, was rather diffuse and had none of the typical earmarks of cardiac accident. His temperature ran between 99° and 100° F., pulse slightly increased, blood pressure from 95 to 100 systolic, and no abnormal findings in the chest were noted. Because of the previous history and the present localized pain in the abdomen, it was thought he had a perforating ulcer of the forme fruste type and he was operated upon. No perforation was found, but the scar of the old duodenal ulcer was quite easily visualized. The following day definite evidences of pericarditis were noted. Recurrence of pain was also observed, and after several weeks the patient made a relatively uninterrupted recovery.

I think it is important that this mistake in diagnosis be commented upon inasmuch as the patient was subjected to a very serious surgical procedure that might have resulted in disaster. Following his operation a cardiogram was taken

and presented conclusive evidence that we were dealing with coronary occlusion. The mistake in the diagnosis might have been obviated had we taken a cardiogram prior to the operation. Frequently, of course, the cardiogram does not reveal any positive evidence within the first twenty-four hours and, therefore, in the presence of a negative cardiogram we must always be extremely cautious in the diagnosis of upper abdominal lesions in an individual whose age is compatible with coronary accident.

Pains from intra-abdominal lesions may best be discussed from the standpoint of the organs involved, especially when the pain pattern is fairly exact.

A typical attack of biliary colic is characterized by severe pain in the right upper quadrant of the abdomen radiating through to the back and usually to the right shoulder blade. The paroxysm usually begins and terminates abruptly. Very commonly there will be a residual soreness over the region of the gallbladder for several days. According to the criteria stated above, for the consideration of pain, we have here a definite point of maximum intensity under the right costal margin and radiation to the right shoulder blade. It cannot, however, be related to a definite physiologic functional disturbance since it seldom occurs regularly following meal taking. It is, however, often precipitated by an excessively heavy meal, particularly one containing fat. There is also associated symptoms of nausea, sometimes vomiting, and an increase in temperature. When jaundice occurs, the diagnosis is much more complete. This typical attack is usually connected with the passing of a gallstone. When obstruction of the cystic or common duct occurs associated with an active infection in the gallbladder, then the accompanying symptoms of shock, high fever and continued pain are evidences of empyema of the gallbladder. A sudden onset of pain with marked rigidity, evidences of shock and infection make the diagnosis more difficult because then perforated ulcer, acute hemorrhagic pancreatitis, coronary occlusion or mesenteric thrombosis must be considered.

Renal colic very frequently presents a typical picture. The colic may be due to kink of the ureter or the passage of a stone or of a stone blocking the kidney pelvis at the ureteropelvic junction. This colic is a paroxysm of pain noted in the flank and frequently radiating downward toward the bladder and into the thigh or into the testicle, penis or labia on the side involved. This pain traverses the field of distribution of the eleventh thoracic to second lumbar spinal segments. Burning and frequency of urination are quite constant. The finding of red cells in the urine is an added diagnostic point. We have observed that distention of the kidney pelvis by retrograde pyelography produces a typical colic. The hydronephrotic kidney of long standing causes little distress unless an obstruction of the ureter, as in Dietl's crisis, occurs. The pain from stone or kinking of the ureter is due undoubtedly to an increased tone and distention of the kidney pelvis or of the ureter itself rather than to direct irritation from the stone on the mucosa. Less typical attacks of pain occur from disturbance of the kidney and require a great deal of care in the differentiation from the more chronic type of distress produced by the colon or by recurrent appendiceal infection.

A woman, thirty-two years of age, complained of pain in the right lower quadrant in the region of McBurney's point for several years. Because of this constant annoying pain and the associated disorder of the colon function, the appendix was removed. The distress originally complained of continued. There was never any sign of acute colic, no frequency or urgency of urination, and no abnormal urine findings; at the time of our examination it was noted that the kidney was easily movable and when placed upon her left side the kidney traveled out to the region of the umbilicus. She was then examined while in the upright position. The kidney was found to be at the level of the crest of the ilium and when pulled downward it was possible to reproduce the pain which she had previously experienced. On advice her kidney was studied both by intravenous urography and retrograde pyelography. A marked ptosis with definite hydronephrosis and associated ureteral angulation were found. Proper measures were instituted and the pain disappeared at once.

I am quite convinced that every patient with chronic recurrent right-sided pain should be studied from the stand-

point of possible kidney involvement. Undoubtedly strictures of the ureter will produce such symptoms.

An uncomplicated peptic ulcer usually produces a typical pain pattern. Here it is extremely important to study the type of pain with relation to the several criteria noted above because in so doing we are able to evaluate to a great extent the nature of the lesion and something of the progressive pathology if and when such changes occur. Distress of ulcer, as we are all quite familiar, may be no more than fulness or present the severe agonizing pain associated with acute spasm or perforation. The pain of uncomplicated ulcer, whether gastric or duodenal, is usually noted in the midepigastrium. It seldom appears in the morning before breakfast, usually occurs an hour or two after meals and occasionally it noted at twelve to two o'clock in the morning. It regularly is relieved by adequate alkali, food, vomiting and aspiration.

When the ulcer becomes complicated by obstruction, perigastritis or perforation, the pain then may vary considerably. In the presence of obstruction it will frequently continue until the next meal. When it is associated with obstruction due to spasm, the pain frequently will be quite intense, but will still be relieved by food and alkali. When obstruction is associated with definite cicatrix formation, a continued secretion is likely to be present and food and alkali may not give such complete relief. Aspiration or vomiting, however, invariably give prompt and complete relief. Perigastritis, or periduodenitis, indicates an inflammation of the peritoneum and here the pain is not always completely relieved by food and alkali; in fact, sometimes it is aggravated. Furthermore, the pain is likely to be accentuated by change of position and also by increased peristalsis.

It is well to remember particularly this fact, that pain of an uncomplicated ulcer, whatever its cause, will be relieved by food, alkali, vomiting and aspiration. If we will use this as a simple procedure for test-out observations, we will usually be able to differentiate very satisfactorily between gallbladder disease and peptic ulcer. The following case report will sug-

gest the varying pathology in ulcer as indicated by the changing pain picture.

A man, aged forty, came to the hospital seeking treatment for "ulcer of the stomach." He stated that he had had symptoms of stomach trouble during most of his adult life. As a young man he had what was called heart burn, occurring several days in succession, always appearing an hour or more after meals and relieved by soda. For this his appendix was removed. Within a few months he had a recurrence of distress that had more the nature of definite pain. This also was present an hour or more after meals. Periods of relief followed by periods of definite pain continued for more than ten years. The pain at first was relieved by food and soda and seldom appeared at night time. Later on, however, the pain was not so completely relieved by the average dose of soda. He was awakened frequently at night time and finally, on occasion, would vomit a large quantity of fluid out of proportion to the amount that he had taken. Vomiting would give complete relief of distress. One night he was suddenly seized with severe pain in his upper abdomen requiring the services of a physician who gave him morphine for relief. He states that the abdomen was extremely sore and tender for several weeks after this attack. He was forced to remain in bed because of the severity of the symptoms for more than a month. Some months after this particular incident he had a recurrence of symptoms similar to those experienced before the abdominal accident. He then for the first time in this long experience of gastric invalidism was given the advantage of an x-ray study. It was found that he had a duodenal ulcer. He was operated upon and a gastro-enterostomy performed. The surgeon stated that the duodenum was immobile, being fixed to the surrounding viscera by dense, thick adhesions. His recovery from the immediate effects of the operation was uneventful. Some weeks later he experienced pains in his abdomen located to the left of the midline. This pain, when it occurred, would radiate downward to the groin. Occasionally he would vomit. He obtained relief from the distress by vomiting and by the taking of alkali. In fact, he obtained complete relief for a time on a carefully supervised diet. Subsequent examination of the gastro-intestinal tract revealed the stomach emptying through the gastro-enterostomy stoma and evidence of spasm in the stoma with distinct pain over this area. He was operated upon again and a jejunal ulcer resected.

Study of this patient reveals variations in the character of the pain based upon the changes in the pathology that developed from time to time. At first the pain and distress were that of an uncomplicated ulcer. Later the pain picture changed with the presence of obstruction. Later still the acute attack of pain was definitely that of a perforating ulcer of the duodenum and finally the pain produced by the complication from the perforating jejunal ulcer. When the pain of

ulcer shifts in its position from the midline to the left, one is usually dealing with a penetrating gastric ulcer or, more likely still, a jejunal ulcer. We have noted, as have others, that pain of a penetrating or perforating jejunal ulcer frequently radiates downward to the groin and, as Dr. Ralph Brown reported, actual radiation into the left testicle. When pain is felt in the back, it usually means that the simple ulcer has become complicated by perigastric or periduodenal adhesions or that there has occurred a forme fruste type of perforation. Relatively acute pain recurring regularly day after day usually means spasm of the pylorus, while gradual decreasing severity of pain over a period of years suggests a scarring of the ulcer area. There is definite prognostic value in the proper and careful study of pain.

Abdominal pain is one of the commonest complaints, often the chief symptom, of the gynecological patient. It is usually low on one or both sides, less likely in the midline and seldom above the umbilicus. Pain of tubal and ovarian lesions is noted regularly over the brim of the pelvis and frequently on the corresponding side of the diseased organ. It is frequently precipitated by the onset of the menstrual flow. Repeated torsion of small ovarian cysts may frequently account for recurrent low abdominal pain. When the pain is generalized over the lower abdomen, it suggests the possibility of tuberculous peritonitis. Ectopic pregnancy and pyosalpinx are frequently confused with appendicitis. A pelvic examination may be the only means of definitely differentiating the conditions. On the other hand, sigmoid spasm, if prolonged and if of unusual severity, may be extremely confusing.

Appendicitis is invariably associated with some degree of pain. We are accustomed to accept the diagnosis of appendicitis on the basis of generalized abdominal pain, perhaps accentuation in the epigastrium and then gradually localizing in the region of McBurney's point with an associated local rigidity. The pain may be extremely severe, although as a rule it is accentuated chiefly by pressure directly over the cecum. The appendix alone is involved when the pain

is referred to the epigastric or umbilical region and later on involves the parietal peritoneum when the symptoms localize in the right lower quadrant. The pain of acute appendicitis may be confused with gallbladder or kidney disease, especially when the organ is located retroceally. Likewise, it may be confused with disease of the ovary or tube and particularly in older individuals difficult to differentiate from diverticulitis. When the pain is less severe or when it is associated with disturbances of the colon, particularly with the irritable bowel dysfunction, diagnosis may be very difficult indeed and it becomes obvious that the associated signs and symptoms of appendicitis must be taken into account rather than relying entirely upon the pain picture.

The irritable and spastic colon may produce pain which will mimic the pain of peptic ulcer, gallbladder colic, appendicitis, intestinal obstruction, or pelvic disorders. The pain usually shifts from one section of the abdomen to the other, may be aggravated by food ingestion, cold drink, chilling the surface of the body and often precede a bowel movement. It is induced by or aggravated temporarily by a large water enema. Coarse foods usually offend it. It may be associated with extra-gastro-intestinal pathology, as in thyrotoxicosis and Addison's disease. It is frequently influenced by infection of the gallbladder, appendix, and by irritating lesions about the rectum and anus. It may be confused with lead poisoning, diverticulitis and postoperative adhesions. The possibility of an allergic state must be always borne in mind.

The colon is frequently palpable throughout its entire course and the patient is often quite conscious of the segments involved. The pain may subside and be followed by a sensitiveness and unrest comparable to pain, but of a less severe degree. In long continued irritabilities with or without ulcerations or inflammations there is frequently an associated psychic disturbance which requires the most careful evaluation in order to obtain a successful cure. The more often we meet these particular intestinal invalids, the more we appreciate the factor of mental instability as one most necessary

to treat. Mucous colitis, although manifesting primarily a colon disorder, is invariably associated with a definite nervous makeup. The pain associated with expulsion of mucus is, I think, no different than spasm of the colon in the non-inflammatory colon, and mucous colitis is in reality a highly irritable colon with excess mucous secretion in a highly nervous individual. This conception is essential to a full understanding of the treatment of pain later described.

The control and relief of abdominal pain presupposes not only an accurate diagnosis, but a full appreciation of the structural and functional changes involved.

Since the pain is so important as a diagnostic sign, balanced judgment must at all times be exhibited whenever medication is to be instituted. No treatment for relief of pain must ever be permitted until the diagnosis has been made or at least until it seems reasonably certain that either the further study of the pain symptoms is unimportant or that the emergency demands immediate relief. This particularly pertains to the acute abdomen. The treatment of any symptom is, perforce, secondary to the contemplated treatment as a whole; nevertheless, pain as such is so important to the patient that definite measures must be instituted for its control.

Severe colic or pain of sudden onset is best relieved by $\frac{1}{4}$ grain of morphine given hypodermically. If this does not alleviate the pain, it should be repeated within a half hour. In acute pancreatitis or ruptured peptic ulcer, there is evidence of a definite emergency and since surgery is necessary, scopolamin $\frac{1}{150}$ grain may be added as it not only aids in relieving the mental anxiety, but prepares the patient for the subsequent anesthesia. If a gallstone colic or renal colic is diagnosed and no vomiting is present, $\frac{1}{4}$ grain of morphine sulphate or $\frac{1}{2}$ grain of codeine phosphate may be given by mouth. This is perhaps only justified if the patient is unduly apprehensive about a hypodermic.

Pain from appendicitis seldom requires a sedative and if it is severe enough, should then only be relieved when operation has been definitely decided upon. Pain due to torsion of

an ovarian cyst or fibroid on its pedicle or due to ruptured ectopic pregnancy requires morphine as early as feasible.

In general, when a diagnosis of an abdominal accident is made surgery, when not contraindicated, should be instituted as soon as possible. When that decision has been arrived at morphine, pantopon or codein should be used to relieve the patient of all the suffering possible. One need not fear any harmful effect on the subsequent anesthesia.

In general or local peritonitis, where for some reason immediate operation is not deemed advisable, morphine should be used freely. Since the pain is frequently the sign of intestinal activity, it may remain as a guide of therapy. Peristalsis should be kept at a minimum of activity. In local peritonitis, as found in diverticulitis, milder sedatives may be used, especially when the sigmoid is involved.

The postoperative "gas" pains should, I believe, be treated more conservatively than is the usual practice. This scarcely requires consideration within the scope of this paper, but perhaps these few comments are in order. It is true that at times such vigorous enemas as milk and molasses or the commonly used 1-2-3 enema may give good results by producing peristalsis and the subsequent expelling of gas. These pains are usually due to lack of peristalsis and distention of loops of intestine. This dysfunction disappears within a few days after the normal tone and function have returned. Continued injections of various irritating fluids can certainly result in prolonged gas pain disturbances or worse still an aftermath of colon irritation which the patient will carry for a long time. It has been my experience that a rectal tube, an opiate, pituitrin, or prostigmin along with heat to the abdomen, when acceptable, will do as much or more good than laxatives and enemas and be followed by less intestinal invalidism later.

The management of the more chronic and recurrent abdominal distresses and pains requires the consideration of several therapeutic measures; namely, drugs for sedative and antispasmodic effect, diet, physiotherapy, and psychotherapy. These four measures are involved in varying degrees in the

proper and successful handling of peptic ulcer, irritable colon, chronic constipation, ptosis of the kidney and the other disorders mentioned.

In simple uncomplicated peptic ulcer pain is almost invariably relieved by adequate alkali and food. By adequate alkali is meant sufficient amount to neutralize completely the acid gastric juice. A powder containing sodium bicarbonate 30 grains and calcium carbonate 30 grains taken in $\frac{1}{2}$ glass of water will produce relief within five to ten minutes. One glass of milk and a few crackers will produce the same results. However, if the ulcer is in a fairly active state, the pain will recur after a time or usually again after a later meal and, therefore, the powder must be repeated. This procedure will not be effective as a management nor should it be continued as such since the patient will not be cured, but will be lulled into a state of false security. The control of the pain of peptic ulcer will be incorporated in the general management. In a properly managed ulcer diet the pain usually disappears within a day and seldom is it noted after the third day. In fact, when present after six to eight days, some complication should be suspected and searched for. When night pain is noted, alkalis should be given every hour or two throughout the night. This pain indicates obstruction at the outlet with an associated continued secretion. This latter complication will best be controlled by emptying the stomach with a tube at 10 P. M. and 1 or 2 A. M. Frequently pain that persists at night will be promptly relieved by instituting this procedure for three or four successive nights. Coarse and irritating foods frequently precipitate trouble and, therefore, should be avoided.

Other drugs than alkalis are seldom needed for control of pain. Occasionally tincture of belladonna in 10-minim doses three times daily is used. More often a sedative of 10 grains of sodium bromide given three times daily or a barbiturate will help control the apprehensive patient. Papaverin hydrochloride $\frac{1}{4}$ grain. elixir phenobarbital $\frac{1}{4}$ drachm taken three to four times daily will be effective.

I have never been convinced that atropine in safe doses could be used long enough to demonstrate any great clinical benefit.

In the forme fruste type of perforation, where operation is not considered, the above-mentioned medications are used and in addition hot wet packs to the abdomen are effective. Aside from alkali no part of the management of ulcer is so essential and withal as poorly appreciated as rest and relaxation. If this could be definitely made a part of the management of all early ulcers, less ulcer invalids would develop.

The pain and distress of an irritable colon are due to a disorganized functioning of that organ. Varying states of tension and spasm in the musculature are present with resulting colic, pain, soreness and unrest. These subjective symptoms are best managed by such measures as will allay peristaltic unrest and tend to develop an orderly functioning of the colon.

For the acutely persistent pain or spasmodic colic, the patient is placed at absolute rest and heat is applied to the abdomen in the form of hot wet packs, hot water bags or electric pads. Tincture of opium 5 minims or camphorated tincture of opium 30 minims are given especially if there is an associated diarrhea. Codein or morphine are seldom necessary and then not to be given without the greatest certainty of diagnosis. Cathartics should never be given. The diet should consist of low cellulose residue as warm or boiled milk, soft eggs, toast and cooked cereals. As the colon becomes quiet, cooked fruits and cooked vegetables (all strained) may be given in increasing amounts until a normal diet is attained. This may require days or weeks of diet restriction and of careful food selection. Ice cold drinks, excessive fruit juices, bran, beer and buttermilk and specific foods to which the patient knows he is sensitive should be avoided. In the less severe pain the same dietary scheme should be used. Tincture of belladonna 10 minims and sodium bromide 10 grains, each three times daily after meals, will usually quiet the pains of flatulence and peristaltic activity. At times atropine $\frac{1}{150}$

to $\frac{1}{75}$ grain repeated four times daily will be more effective. If continued over any great length of time it may be found necessary to increase the dose. Syntropan has recently been advocated as an excellent antispasmodic.

The management of the type designated as mucous colitis is for all practical purposes the same. It seems scarcely ever necessary to resort to colonic irrigations or large water flushings either for treatment or the control of symptoms of either the ulcerative, noninflammatory or functional disorders of the colon. Should impactions develop due to improper management, enemas will be necessary for temporary relief, but this complicating trouble is obviated by the use of 2 to 3 ounces of warm olive or cottonseed oil as a retention enema when the bowel fails to move or the movement is hard and dry.

No specific dietary measures are to be followed for relief of pain as such in the treatment of disorders of the gallbladder, kidney or appendix or the several other conditions mentioned before.

Physiotherapy is considered frequently in management of the various chronic disorders of the abdomen not only as to treatment, but especially in the control of pain. The management of pain under consideration seldom requires infra-red or ultraviolet radiation and I have been so regularly disappointed in diathermy as a therapeutic agent in disorders of the colon as to abandon its consideration entirely.

Ice-bags to the abdomen in acute appendicitis remain in favor largely because presumably it is thought to limit the progress of the pathological process and also since it does seem to relieve pain. Heat to the abdomen will relieve pain in this disease, but is not to be recommended. Cold packs do not seem to be effective in any of the other disorders here considered.

Heat in the form of hot wet packs, hot baths, or electric pads comes nearer being the most specific physiotherapeutic measure available.

Hot wet packs should be applied continuously in local peritonitis of pelvic origin or in acute diverticulitis. Pain is

often readily controlled. They should be used in perigastitis and where spasm and pain of ulcer are difficult to control. A hot tub bath of five to ten minutes' duration may be resorted to in the presence of kidney or gallbladder colic or severe spasm of the colon. The hot-water bag or electric pad is regularly used for the acute colics, but especially in the more chronic recurrent pains of the colon. In the latter condition heat is applied one-half to one hour with a discontinuance for a like period of time, but to be continued for a longer time than the duration of the distress. Heat to the abdomen in the chronic intestinal invalid offers to that patient the greatest solace.

Massage is seldom to be recommended, although occasionally very light stroking over the colon by the experienced hand seems to be effective. Certainly deep, vigorous massage will aggravate rather than lessen the pain of colon origin. It should not be recommended in any other condition. I have suspected that the good noted by the patient has been largely psychic.

Pain from ptosis of the kidney or, as occasionally occurs, from ptosis of the stomach with an associated duodenal angulation will be relieved often by the wearing of a properly fitted supportive belt or corset. Special pads, cushions and straps seem to lend little more to the effectiveness of the corset than can be expected to come from the general support and relief from the tension on the attachments of the various organs.

The successful physician succeeds best who practices, knowingly or unknowingly, some measure of psychotherapy. The soothing influence from the comforting physician is never to be forgotten as one of the most effective therapeutic measures and pain in most instances is markedly increased by the fears of uncertainty. If the origin of pain can be definitely ascertained and proper measures of control instituted, a great part of the battle is won.

CLINIC OF DR. J. P. GREENHILL

COOK COUNTY HOSPITAL

RELIEF OF PAIN ARISING IN THE FEMALE PELVIS

PATIENTS are more grateful for the relief from severe pain than for anything else which physicians can do for them. Fortunately in most instances, the cause of excruciating pain can be determined and removed. Thus, for example, the severe pain due to appendicitis, ruptured ectopic pregnancy, ruptured hollow viscus, etc., may be relieved by surgical operations. In other instances, excruciating pain can be relieved by the opiates as in cases of gallbladder colic, renal colic, etc. However, there are many instances where the source of annoying pain cannot be found or, if determined, it cannot be removed or satisfactorily relieved.

In the female pelvis the genital organs are a frequent source of severe pain. In inflammatory diseases of the tubes and ovaries, especially those due to gonorrhea, the pain may usually be relieved by conservative treatment. However, in many instances an operation is necessary to bring about relief. Following such operations, most of the pain disappears. Less frequent causes of pain in the pelvis are fibroids which produce pain by pressure on other organs or submucous fibroids which the uterus attempts to expel.

Endometriosis is another pelvic condition which usually produces pain. The pain associated with this abnormality as well as that due to fibroids may be relieved by surgical measures and sometimes by radiation therapy. Ovarian tumors occasionally cause pain and this pain may also be eliminated by removal of the growths.

There are, however, types of pain in the pelvis which are difficult to relieve. These are the severe dysmenorrheas, the

intractable pain associated with carcinoma of the cervix and other pelvic organs, and pain which occasionally follows operations in the pelvis and lower abdomen.

Dysmenorrhea.—Dysmenorrhea is generally divided into two types, primary and secondary. The latter is caused by pathologic conditions in the pelvis, usually uterine fibroids, endometriosis, or salpingitis. Surgical correction of the pathologic disturbance usually cures the menstrual pains. Primary dysmenorrhea, on the other hand, is not associated with any abnormality in the pelvis and its treatment is one of the most baffling problems with which physicians have to deal. Almost every type of analgesic drug has been employed to relieve primary dysmenorrhea, but not one has given any semblance of uniform success. There is no unity of opinion concerning the exact cause of this type of pain. Novak and Reynolds are of the opinion that the immediate cause of dysmenorrhea is an exaggerated contractility of the uterus, manifested by pain if the pain threshold is lowered or if there is an actual imbalance between the two hormones that appear to regulate this. These two hormones are the follicular factor, the normal stimulant of uterine excitability and progesterin, the normal inhibitor. Hence, Novak says in cases of dysmenorrhea it is advisable to administer biologic uterine antispasmodics and the one recommended is the luteinizing principle obtained from the urine of pregnant women. Other individuals believe that the strong pains associated with menstruation are due to an imbalance in the pelvic sympathetic system. Perhaps both factors are involved.

Because the exact etiology of dysmenorrhea is still unsettled, treatment is in most cases empiric and not satisfactory. There are a large number of young women who suffer inexorably every month in spite of what is prescribed. For those who are not helped by medication, physiotherapy, psychotherapy, dilatation and curettement and other measures, resection of the superior hypogastric plexus yields excellent results because in the large majority of cases instant relief is obtained. This operation will be described shortly.

Pain Due to Pelvic Malignancy.—Carcinoma of the uterine cervix is one of the most serious afflictions a woman can develop because at least three out of every four women who have the disease die from it. Furthermore, nearly all of these women suffer excruciating pain during the latter part of their lives and in a large proportion of cases the pain is constantly present both day and night and is almost unbearable. This is due to the fact that the sensory nerves become involved in the malignant growth. There are at present three means of relieving this pain. The first and the one almost exclusively used at present is the administration of derivatives of opium, chiefly morphine. However, there are disadvantages to this form of therapy, particularly the necessity of giving constantly increasing doses as the patient's tolerance increases, the nausea and vomiting which some women experience, the idiosyncrasy of others, the addiction which many women develop, the excitement produced in some and the expense for poor patients. The second method of giving relief from pain is surgical and consists essentially of pelvic sympathectomy and chordotomy. The third means of relieving pain consists of blocking the nerves which conduct pain sensation. This may be accomplished by a number of different solutions, but alcohol is the most commonly used.

Intraspinal Alcohol Injections.—The simplest of the aforementioned methods is the intraspinal (subarachnoid) injection of absolute or 95 per cent alcohol. It is based upon the idea of destroying some of the nerve fibers in the posterior nerve roots, these being the roots which convey the sensation of pain. Injection of absolute or 95 per cent alcohol into the subarachnoid space will prevent all painful peripheral stimuli from reaching the medullary centers, even if the stimuli act at the level of the spinal ganglia, the intervertebral foramina or the spinal roots. The technic of the injection is as follows: No preliminary medication is given because we wish to observe the immediate effects of the injection. Most patients with advanced carcinoma of the cervix and other genital organs have much more pain on one side than on the other. The

patient is placed on the side opposite to that where most of the pain is present. A pillow or pad is placed under the pelvis and side to elevate the sacral and lumbar portions of the spine, her back is arched as much as possible, her body turned somewhat ventrally and the head lowered slightly. By placing the patient in this attitude we raise the sacrolumbar region of the spine to the highest level and at the same time make the posterior or sensory nerve roots lie horizontally. The anterior or motor nerve roots come to lie in a plane which is usually out of reach of the alcohol. Even if the motor nerves are not removed from the field of the alcohol, they are not often affected because sensory nerves are more susceptible than motor fibers to the effects of alcohol.

Someone should hold the patient in the proper position. A weak solution of iodine or other antiseptic is applied over the lumbar and upper sacral regions. In most of my cases the fourth lumbar interspace is selected for the injection of alcohol and the results have been highly satisfactory. An ordinary lumbar puncture needle with a stylet is used. The needle is injected into the desired interspace just as for an ordinary lumbar puncture and I prefer not to use novocain in the skin before inserting the needle. After the needle is in the subarachnoid space, as evidenced by the flow of spinal fluid, 0.5 cc. of absolute or 95 per cent alcohol is injected into the cerebrospinal fluid. For this purpose it is best to use a tuberculin syringe so as to be sure not more than 0.5 cc. is injected. Furthermore, the alcohol must be injected very slowly, drop by drop, taking about two minutes for the injection of the 0.5 cc. This will avoid a mixture of the alcohol with the spinal fluid. The alcohol rises immediately to surround the posterior roots because the specific gravity of alcohol is about 0.806, whereas, that of the spinal fluid is 1.007. No attempt should be made to draw spinal fluid into the syringe to mix it with the alcohol because this is exactly what is *not* wanted. After the injection is made the needle is withdrawn and the puncture hole covered with sterile gauze and adhesive. Before the injection is completed, the patient will complain that the

upper leg feels numb or hot and that she cannot move the leg. The numbness is almost routinely experienced after the injection, but disappears spontaneously after a few hours or few days in most of the cases. In spite of what the patient says concerning her inability to move the leg, she can easily move it when requested to do so. At the same time that the patient informs us of the numbness she also often tells us either voluntarily or in answer to our query that her pain has disappeared. The longer the patient is permitted to lie on her side, the better the results. Hence I now keep my patients on their side for two hours after the injection. Then these women are permitted to get up and walk around. Some find difficulty in getting up from a chair because their "leg is asleep." Sometimes the leg feels heavy and the patient experiences some trouble in walking up steps because the knee flexes readily. These sensations usually wear off in a few hours, although in some women they last a number of weeks. Nearly all of my patients went home within three hours after the injection and no ill effects have been observed from this procedure. It is perhaps best, however, to keep the patient in a hospital for at least twenty-four hours.

If the patient has pain on both sides, an injection is made a week later with the patient lying on the opposite side. The same amount of alcohol is injected.

Formerly I restricted the subarachnoid injection of alcohol to patients with hopelessly advanced cancer. Until we knew more about the effects of absolute and 95 per cent alcohol on the spinal cord I did not extend the use of this procedure to other cases. Recently we have obtained striking results in cases of pruritus vulvae.

Thus far my associate, Dr. Herbert E. Schmitz, and I have performed alcohol injections on 45 women who have advanced cancer of the cervix. We have completely or greatly relieved all but four of these patients. Some of these women have been free from pain for as long as ten months. A few who had pain on both sides and who experienced almost immediate relief on

one side after an injection, asked that the injection be repeated on the other side.

Pelvic Sympathectomy.—Another procedure which has yielded excellent results in cases of hopelessly advanced cancer of the genitalia is the operation known as pelvic sympathectomy, resection of the presacral nerve or resection of the superior hypogastric plexus. This operation may be performed by anyone trained to do abdominal surgery. The risk involved is slight, the technic is not complicated and local anesthesia may be used for most if not all of the operation, if desired.

The portion of the sympathetic nervous system which is removed is that known as the presacral nerve or superior hypogastric plexus. This plexus can readily be found if one looks for a triangle the base of which corresponds to a line uniting the two common iliac arteries at the level of the sacral promontory, the sides being these arteries and the apex of the triangle being the point of bifurcation of the aorta. This triangle occupies the lower third of the fourth lumbar vertebra, the last intervertebral cartilaginous disk and the fifth lumbar vertebra. The base of the triangle is about 7 cm. in length and the distance from the base to the apex is almost 6 cm. A large part of the left side of the triangle is occupied by the left common iliac vein, which arises from the inferior vena cava and passes downward from beneath the right common iliac artery to accompany the left common iliac artery. The triangle is divided vertically into two equal halves by the middle sacral artery, which arises from the back part of the aorta just at its bifurcation and courses straight down to the upper part of the coccyx. Since this vessel is easily felt through the peritoneum it is often mistaken for the presacral nerve, which runs parallel to it. From the origin of the inferior mesenteric artery down to the bifurcation of the aorta, the sympathetic nerve fibers lie on the aorta, separated from it only by a layer of thin connective tissue. The branches of the plexus which accompany the left common iliac vein are separated from this vessel by areolar tissue, making elevation of the nerve easy. However, as the nerve fibers go still far-

ther down, they lie on the perichondrium of the last lumbar vertebra, and the cartilaginous disk between this vertebra and the sacrum. At this point the plexus lies above the middle sacral artery and veins.

The entire triangle is covered with peritoneum; hence the nerve plexus lies between the peritoneum and the underlying bones. The fibers are not adherent to the peritoneum, but are separated from it by more or less fatty tissue, depending on the obesity of the patient.

Two questions may properly be raised. One is whether the large fibers of the sympathetic system are really sensory. Ranson says that proof of this was offered more than twenty-five years ago by Edgeworth and that he confirmed Edgeworth's observations. If the roots of the spinal nerves are cut proximal to the spinal ganglions, all the motor fibers degenerate, but the sensory fibers remain.

The hypogastric plexus produces vasoconstriction of the blood vessels of the internal genital organs and it inhibits the secretion of the genital glands, whereas the parasympathetic nerves produce the opposite effect. Section of the superior hypogastric plexus does not alter the normal menstrual cycle nor does it interfere with uterine contractions during labor. Likewise, section does not produce glandular atrophy or any disturbances in the motor function of the bladder or rectum. Therefore, the nerve fibers of the superior hypogastric plexus are sensory and not motor. They carry the sensations from the internal genital organs to the medullary centers. Hence resection of the portion of the superior hypogastric plexus above the hypogastric ganglion is a simple way of relieving a patient of severe pain arising in the pelvic organs.

The second question that may be raised concerns the possible harm done by removing a portion of the sympathetic nervous system. Ranson states that Cannon and his students completely removed from cats "the sympathetic chain on both sides, from the highest cervical to the lowest sacral ganglion. Such completely sympathectomized cats have lived under laboratory conditions for many months. Everything indicates that

almost any part of the sympathetic system can be removed without seriously endangering life."

Technic of Pelvic Sympathectomy.—The technic of pelvic sympathectomy is as follows: The patient should be placed in the Trendelenburg position after a midline incision has been made from the umbilicus downward toward the pubis for about 10 to 12 cm. After the peritoneal cavity is opened, the small intestine is packed off and the sigmoid and rectum are pushed to the left side and held there with a wide retractor. The uterus, adnexa and bladder may then readily be inspected and palpated. One may detect a complication, that can be remedied by a surgical procedure. The region of the lower two lumbar vertebrae and the upper part of the sacrum is exposed to view. In thin women, it is possible in some cases to see the presacral nerve immediately beneath the peritoneum. Whether or not the nerve is seen, the parietal peritoneum above and in the middle of the sacral promontory is elevated and incised with scissors. This incision is extended upward for about 4 or 5 cm. and for a similar distance down along the sacrum. When the peritoneal flaps are pulled aside, a fibrocellular connective tissue layer will be exposed, covered by more or less adipose tissue. This tissue can easily be separated from the peritoneum and the lower end of the aorta without danger. It is in this layer that the presacral nerve lies. With an aneurysm needle the tissue is elevated at the bifurcation of the aorta and the dissection is carried to a still higher level. As this is done, it will be found that in most instances the tissue spreads out triangularly. The middle sacral artery should be pushed away from the nerve, but if it is injured it can readily be ligated.

After the dissection is carried as high as it is desirable to go, the layer of nerve tissue is separated from the underlying tissue down past the sacral promontory into the pelvic cavity. In this region the plexus has divided into two hypogastric nerves; hence it is necessary to dissect one of these nerves at a time. At least 2 or 3 cm. of each hypogastric nerve should be resected in addition to 4 or more centimeters

of the superior hypogastric and the intermesenteric plexuses. The fibrous tissue layer, which contains the hypogastric nerves, is much more resistant than that which contains the presacral nerve. As the dissection is carried out, nerve filaments projecting outward will be encountered. These should be followed as far laterally as possible before they are cut. In most instances, ganglions will be included in the resection. The dissected tissue should preferably be removed in one piece. It is not necessary or advisable to ligate the presacral nerve or the hypogastric nerves before cutting them, because the only blood vessels in intimate contact with them are insignificant vasa nervorum. Very rarely does one encounter bleeding that requires more than simple temporary pressure to check it. (When the mesosigmoid is very short, care must be exercised to avoid injury to the inferior mesenteric vessels.) After the nerve is dissected, the posterior parietal peritoneum is sutured with plain catgut and the abdominal wall is closed in the customary way.

Thus far my associate and I have performed 50 sympathectomies. We have found that if all women who have excruciating pain associated with carcinoma of the cervix are subjected to this operation only about 50 per cent will be relieved of their pain. However, if the patients are properly selected almost all will be freed of their pain.

The women who can definitely be relieved of their suffering by sympathectomy are those who have pain in the middle of the lower abdomen, pain low in the back, rectal tenesmus, bladder pain and pain associated with vesicovaginal fistulas. The women who cannot be helped much by sympathectomy are those who have pain in the sacrum due to fixation of the parametrium, pain referred from the region of the sacro-iliac joint into the thigh posteriorly and laterally, pain down the anterior surface of the thigh due to involvement of a gland in the obturator canal and pain due to hydronephrosis and hydro-ureter.

Pelvic sympathectomy is also curative of most cases of intractable dysmenorrhea where every form of therapy has

been tried and failed. Naturally this form of treatment for menstrual pain is heroic and hence it should be used only as a last resort.

Chordotomy.—The operation known as chordotomy should be attempted only by one skilled in neurologic surgery. The operation consists in the removal of a number of laminae, opening the dura mater and incising one or both anterolateral columns of the spinal cord as necessary. If the incision in the cord is not accurately placed, the pain may not be completely relieved because insufficient fibers were sectioned or the motor pathways (pyramidal tracts) may be damaged, resulting in paralysis of the legs and interference with sphincter control. I have had no personal experience with this operation.

Pain Following Operation.—There are occasional instances where distressing pain either arises or persists following an operation on the pelvic organs or in the lower abdomen. If a second operation is performed because of the pain it seldom gives relief because usually no cause for the pain can be found. In most of these patients, relief from the pain can be obtained by a pelvic sympathectomy.

Conclusion.—Any procedure which will relieve women of excruciating or constant pain is worthy of a trial. For the severe pain which is associated with malignancy of the female genitalia, drugs are unsatisfactory. There are three operations which can give most of these women relief. In the order of their simplicity they are the intraspinal (subarachnoid) injection of absolute alcohol, pelvic sympathectomy and chordotomy. The subarachnoid injection of alcohol should be tried first because it entails the least risk and gives relief in the vast majority of cases. Resection of the superior hypogastric plexus is more risky because it necessitates opening the abdominal cavity, but the risk is slight and the operation can be performed by anyone with surgical experience. Chordotomy on the other hand requires special technical knowledge.

In addition to the unfortunates who have advanced carcinoma there is a group of women who suffer inexorably during each monthly flow. For those who have not been helped by

medication, dilatation and curettement and other means, the operation of pelvic sympathectomy offers instant relief in the majority of cases. Likewise this operation will prove helpful in the cases where annoying pain follows an operation in the pelvis.

CLINIC OF DR. ISADORE PILOT

COOK COUNTY HOSPITAL

SEPTIC SORE THROAT: CLINICAL AND BACTERIOLOGICAL CONSIDERATIONS

A SEVERE type of tonsillitis is usually designated as septic sore throat. Such marked reactions in the throat are particularly striking in infections due to the hemolytic streptococci. From the point of view of serious and fatal complications the significant septic sore throat has been observed in epidemic form, as milk-borne septic sore throat. Most sporadic cases appear as a mild sore throat or tonsillitis, but occasionally a similar intense type is encountered resembling in severity the epidemic form but not related to milk. The complications in such sporadic cases are often serious and deserve our special consideration.¹

Acute throat infections present an extremely variable clinical picture. Several factors determine the local and general symptoms. These are, the virulence of the organisms, the dosage of these bacteria, the amount of lymphoid tissue in the oropharynx and most important the reactivity of the patient. Variations in these factors result in either mild or severe sore throat. A large dose of virulent streptococci in a patient with considerable lymphoid tissue and a lowered general resistance lead to a marked sore throat and general symptoms of sepsis that are characteristic of septic sore throat.

Etiology.—The bacteria most often involved in throat infections are the hemolytic streptococci. In our experience 50 per cent or more of the sore throat encountered in daily practice appear to be due to the streptococci. Apparently all human types of *S. hemolyticus* are responsible. The strep-

tococci yielding scarlet fever toxin cause sore throat with a characteristic rash of scarlatina in susceptible persons. In the Dick negative the streptococci may still be responsible for sore throat of a variable severity. Severe septic types are often associated with the scarlet rash and in their tendency to complications and sequelae septic sore throat and severe scarlet fever behave alike. The streptococci of erysipelas are also capable of producing sore throat. These strains are more difficult to identify. Erysipelas may originate from these streptococci invading the skin possibly through an abrasion about the nose or ear, particularly if there is a sinusitis or purulent otitis media that complicates the throat infection.

The most severe type is observed in acute throat infections due to the encapsulated mucoid hemolytic streptococci known as *Streptococcus epidemicus* (Davis). These peculiar properties identify these streptococci readily and have aided us greatly in investigating sporadic sore throat. In milk-borne epidemics these streptococci have always been the source of the mastitis in the cow whose udder sheds millions of these bacteria per cubic centimeter of milk. When raw milk containing *S. epidemicus* is consumed the dosage of infection is massive and a very severe type of sore throat infection results. Serious complications and an occasional death are associated with most milk-borne epidemics. In sporadic cases due to *S. epidemicus* the mode of infection is not through milk but through carriers or active cases. The dosage of the infecting bacteria is much smaller therefore, than in the epidemic type and the reaction of the throat milder. Occasionally the sore throat in the sporadic case may be severe and dangerous. Indeed when a very severe sore throat is observed, the encapsulated streptococci should be suspected. In a series of streptococcic sore throats of the sporadic type 10 per cent of the strains proved to be *S. epidemicus*. The complications and sequelae in this smaller group were more numerous and serious than in the other 90 per cent.²

A large number of the streptococci causing sore throat are not identified with *S. epidemicus*. *S. erysipelatus* or *S. scar-*

latinae. Little is known about their epidemiology and distribution. They may have considerable virulence and may cause sore throat and complications like that of the specific streptococci.

Among the organisms other than streptococci causing sore throat the pneumococci are most serious and often not recognized. These encapsulated diplococci are often very virulent and responsible for an infrequent but severe sore throat that may be very septic in its behavior. In two instances the pneumococci were recovered from the throat and the suppurative lesions of the neck in patients who were desperately ill. One succumbed and at autopsy the pneumococci were found in the pus associated with an extensive thrombophlebitis of the common facial vein with its tributaries, and in the embolic abscesses of the lungs. *Staphylococcus aureus* was isolated in pure form in four cases of sore throat.² Together with the nonhemolytic streptococci they are the cause of a mild form of sore throat. The diphtheria bacilli and Vincent's spirochetes are responsible for a characteristic variety of sore throat, but often the associated streptococci and pneumococci may modify the throat condition and render the condition more septic.

The essential changes in septic sore throat occur in the lymphoid ring of the pharynx. The faucial tonsils become enlarged, edematous and purulent exudation develops on the surface and in the crypts. If the faucial tonsils have been previously removed the lymphoid tissues of the pharynx and at the base the tongue become similarly involved. The spread of infection may be in one of several directions. The extension through the nasopharynx, the eustachian tube, middle ear, mastoid and meninges has been well recognized and emphasized. The pathogenesis of general sepsis has been less clearly understood. So-called "primary streptococcus peritonitis" has been ascribed to a primary hematogenous infection from the throat. Recent studies have pointed out the possibility of the streptococci passing through the depressed gastric juice unharmed to the intestine where they migrate

through the wall to the peritoneum. The spread to the neck and large veins has also been recently pointed out. Fatal cases of septic sore throat have been assumed to be the result of a septicemia from the throat, but careful study has shown that many develop sepsis from a thrombophlebitis that extends from the veins of the tonsils to the common facial and jugular vessels. The streptococcic pneumonia may therefore be embolic in origin, as well as the result of aspiration or lymphatic extension along the bronchi.

Symptoms.—It is needless to describe the symptoms of ordinary sore throat, but the striking features of the more severe and septic cases should be pointed out. At the onset the fever may be high and pulse very rapid. In one instance the temperature was 107° F. Upon examination early the only finding in the entire examination may be a redness of the lymphoid structures of the mouth. Swelling from edema and purulent exudation develop in twelve to twenty-four hours. White patches and intense redness are noted on the second and third days. The membrane in a streptococcus throat as a rule is readily wiped away although the orifices of the crypts may still appear as white spots after swabbing. The pneumococcus produces a more adherent membrane resembling in this respect diphtheria. Fever and tachycardia are sustained for three to five days and then drop slowly in two or three days. Within this period adenitis, otitis media, peritonsillar abscess, parapharyngeal abscess, cellulitis of the neck, or peritonitis may develop. Complications should be suspected if the patient is unable to open the jaws freely and tenderness and induration appear at the angle of the inferior maxilla. In some instances with suppurative processes in the loose tissue of the neck, the lower jaw may be so restricted in its motion as to render examination of the throat difficult. With complications, the fever and pulse rate remain high and the septic state more marked. A severe chill or chills may be indicative of thrombophlebitic involvement of the veins of the neck. In such instances pains in the chest, signs of

pulmonary involvement may appear quickly and lead to a fatal termination.

In patients without tonsils the clinical picture due to identical bacteria is modified. No doubt tonsillectomized persons have less sore throat, but instead many have "colds" and upper respiratory infections. In these individuals the streptococcus infection manifests itself usually with an abrupt onset, chilliness, fever 102° to 105° F. and rapid pulse. Prostration and muscular pains are marked as in influenza, but the pulse is rapid and not relatively slow in proportion to the temperature. Upon examination there may be no findings except for some redness of the pharynx. On the following day the lymphoid follicles may become swollen and covered with exudate. Soreness of throat as a symptom often is absent or only evident as a raw feeling at the base of the tongue. Cough and chest pains may develop, but the lungs and pleurae yield no signs of involvement. Pleuritis and pneumonia, in spite of these common symptoms, are unusual complications. Adenitis is less common than in patients with tonsils, but otitis media is not infrequent. In our experience cellulitis and thrombophlebitis of the fatal type are observed only in the tonsillar forms of septic sore throat. Persons with tonsillar tags develop sore throat with a clinical picture in relation to the amount of lymphoid tissue still present between the tonsillar pillars. Usually the tonsillar remnants become swollen, red, and covered with exudate.

Complications.—These most often develop during the first week of illness. Occasionally after a period of convalescence of a week or two a recurrent sore throat, fever and complications of adenitis, otitis, etc., may arise. At this stage, as the result of a possible state of hypersensitiveness to the streptococci, polyarthrits, endocarditis resembling the rheumatic type may ensue. In a similar way, erythema nodosum and acute glomerulonephritis may appear as sequelae. In the patients with late complications and sequelae a careful examination of the flora of the throat will reveal the persistence of

the hemolytic streptococci in large numbers in swab cultures of the throat, but none in cultures made of the blood.¹

Diagnosis. The diagnosis of septic sore throat is not difficult. Bacteriological examination to exclude diphtheria is very important. To demonstrate the causative bacteria, particularly the hemolytic streptococci, swab cultures should be made of the exudate of the throat, avoiding contamination from the saliva and sputum. The swab should be streaked on the surface of blood-agar plates and in addition inoculated into melted tubes of blood agar which are poured into petri dishes. The latter method will yield hemolytic streptococci that may be overgrown by other organisms on the streaked plates. The poured plates also yield a more accurate picture of the relative number of streptococci. To bring out the mucoid encapsulated streptococci (*S. epidemicus*) ascites fluid is added to the infusion blood agar in proportion of 1 part of ascites fluid to 5 of agar. In severe cases with complications the *S. epidemicus* is a frequent offender because of the more invasive character of the encapsulated organisms. If sore throat appears in epidemic form, the epidemicus should be suspected and if found milk should be suspected as the source of the epidemic infection. No epidemics have been reported as yet from pasteurized or certified milk. Extensive epidemics continue to be traced to raw milk derived from cattle with mastitis due to *S. epidemicus*.

The diagnosis of streptococcus sore throat may be difficult in connection with tonsillectomized persons. Undoubtedly many person with respiratory infections are designated as influenza which in reality are due to the *Streptococcus hemolyticus*. If clinical features are inadequate for differentiation, a swab culture of the throat for hemolytic streptococci may aid in deciding the true clinical state.

In severe cases with apparent complications the recognition of peritonsillar abscess, thrombophlebitis of the vessels are exceedingly important. A chill, high fever, leukocytosis, inability to open jaws, pain and tenderness in the tissues about the angle of the jaw, all point to serious involvement. The

diagnosis of thrombophlebitis is not easy, but if definite should be made quickly and decisively so that surgical ligations and drainage may be immediately instituted.

Prophylaxis and Treatment.—In the epidemic form the source of septic sore throat is raw milk from a cow with mastitis due to a hemolytic streptococcus identified as *S. epidemicus*. To prevent further spread milk should be boiled until the responsible cow is located and excluded. In the sporadic form, sore throat is spread by contact with patients or carriers of dangerous streptococci. It is necessary, therefore, to isolate acutely affected patients exactly as in scarlet fever. If the patient is placed in the hospital because of the complications, these precautions should be insisted upon in order to protect other patients.

In active management of a patient the same measures are carried out as in ordinary tonsillitis. The patient should be watched closely for the development of complications. No specific antistreptococcus or antitoxic serums are available for all cases and in their absence one would be justified to employ a polyvalent streptococcus serum or even the scarlet fever antitoxin in the more serious cases, particularly when complications develop. In some instances it has been possible to employ convalescent serum or blood transfusion from persons who have recently recovered from sore throat. Our experience with convalescent scarlet fever serum in severe complications from septic sore throat is limited.

The treatment of the suppurative complications of the neck and the thrombophlebitis of the facial veins require the services of a surgeon who has thorough knowledge of the anatomical relationships of the structures of the neck to the lymphoid tissues of the throat. Ligation of the facial and jugular veins in severe septic types with chills may be a life-saving procedure.

Convalescence in sore throat is often neglected and may result in the appearance of complications and sequelae in the third and fourth weeks after the onset. If the throat remains deep red, the tonsils large and edematous, there is good indi-

When a tonsillar infection spreads beyond its original confines, that is, when a tonsillitis becomes a peritonsillar abscess, the new inflammation is confined to the connective tissue above described, between the tonsil and the superior constrictor muscle.

Should one of these extratonsillar inflammations spread and in one way or another pass through the superior constrictor muscle, the process is now in the deep tissues of the neck in an area called the parapharyngeal or pharyngomaxillary space or fossa. It is the invasion of this territory which is characterized by signs of sepsis in addition to other symptoms and which is so dangerous to the life of the patient.

The anatomy of the parapharyngeal space or fossa has been concisely and admirably described by Mosher. "The inner boundary of the fossa is the superior constrictor with the tonsil attached to it. The outer boundary *below* is the internal pterygoid muscle lining the inner surface of the ascending ramus of the jaw and mating the masseter on the outside. The outer boundary *above* is the parotid gland, the gland at this point not being covered with fasciae. Posteriorly, the prevertebral muscles and the prevertebral fascia bounds the fossa. The fossa is divided into unequal parts by the styloid process and the muscles rising from it. These are in front of the great vessels and protect them. On the posterior wall near the middle line on the front face of the second cervical vertebrae, there are two lymphatic glands which drain the nose and the upper pharynx and are in chain with the deep cervical glands."

The anterior or muscular or prestyloid compartment contains no large vessels or nerve trunks. It communicates with the parotid space through a defect in the fascia of the latter and is in close relationship to the submaxillary fossa.

The posterior, vascular or retrostyloid compartment contains the carotid arteries, the jugular vein, the glossopharyngeal, vagus, hypoglossal, spinal accessory and the cervical sympathetic nerves.

It is clear that pus in the posterior or vascular compart-

ment, hence, has a clear pathway from the skull and its contents above, to the mediastinum below.

There are at least three ways by which a tonsillar or peritonsillar infection may invade the parapharyngeal space. The first is by means of a retrograde thrombophlebitis of the tonsillar veins to the internal jugular vein. The second is by

FIG. 127.—Cross section of the neck at through the second cervical vertebra showing the pharyngomaxillary or parapharyngeal space. (After Mosher.) 1, Parotid gland; 2, parapharyngeal space; 3, masseter muscle; 4, internal pterygoid muscle; 5, great vessels; 6, lymph nodes; 7, prevertebral muscles; 8, superior constrictor muscle; 9, tonsil.

way of a lymphangitis and lymphadenitis producing, because of the close attachment of the deep cervical glands to the internal jugular vein, first of all a phlebitis and then a thrombosis of the vein. The phlegmonous changes following a lymphangitis may also attack the veins secondarily. Finally, by direct extension, through the superior constrictor muscle, pus

from a peritonsillar abscess or pus produced by breaking down of inflamed glands, may involve the fossa and bathe its contents, attacking with ease the jugular vein because of its thin walls. Combinations of all these three types probably exist in most instances.

Fig. 128.—Dissection of lateral aspect of neck and pterygoid region. (After Bock.) 1, External pterygoid muscle; 2, internal pterygoid muscle; 3, digastric muscle; 4, stylohyoid muscle; 5, hyoid bone; 6, external carotid artery.

The symptomatology of parapharyngeal space infections may be best handled, perhaps, by describing a typical case. Following an attack of tonsillitis, a patient develops a peritonsillar abscess. The usual treatment directed toward this condition fails to give speedy relief. Inability to open the mouth widely or trismus appears. Now trismus is a common

symptom of peritonsillar abscess, but it disappears quickly after drainage has been instituted. Its persistence, in spite of adequate drainage, or its reappearance after having previously disappeared frequently means that the infection has spread beyond the usual area involved in the ordinary quinsy. Its presence in parapharyngeal space infections is due to an inflammatory infiltration involving the internal pterygoid muscle which forms one of the walls of the space.

Fig. 129.—The parapharyngeal space from behind. The pharynx has been opened. (After Bock.) 1, Internal pterygoid muscle one of the boundaries of the space; 2, parotid gland, showing its close relationship to the space.

Fever soon appears. It is usually septic in type, but may be high and continuous. Chills are usually present and come with increasing frequency. A chill at the onset of a tonsillitis or peritonsillar abscess is not uncommon. Repeated recurrence of chills, however, is an ominous sign, and should cause the physician to extend every effort to arrive at a satis-

factory explanation. He must be sure to rule out leukemia, agranulocytosis, pneumonia and all other conditions which could produce this state of affairs.

Most of the time in addition to above symptoms, a brawny induration develops in the neck about the angle of the jaw. Rapidly progressing types and those in which the chief pathology is a retrograde thrombophlebitis from the tonsillar veins to the internal jugular vein may show little or no external swelling in the neck. They may, however, show some tenderness along the course of the vein. The more slowly progressive and benign forms, as a rule, are accompanied by the above described induration. Careful inspection of the pharynx, furthermore, may show some bulging of the lateral pharyngeal wall on the affected side, and the homolateral soft palate may be sluggish in its movements. In addition, there will be considerable pain and difficulty on swallowing.

Having established to his satisfaction that the deep tissues of the neck have been invaded, what is the surgeon to do? The treatment resolves itself chiefly into two parts. Pus is to be evacuated and a thrombosed jugular vein must be ligated or rather resected. In most uncomplicated instances, adequate drainage is sufficient to cause a disappearance of the symptoms. If, following drainage, there is not the expected relief, the internal jugular vein must be inspected and properly handled.

In those cases wherein the pathology is primarily a thrombosis of the internal jugular and there is no evidence of pus in the parapharyngeal space, one proceeds at once to the resection of the vein.

Some authorities insist that in addition to the above the tonsil on the diseased side should also be removed. In the event both tonsils are involved, it becomes more difficult in the absence of external signs to determine which internal jugular vein is involved. It is recommended under these circumstances first to explore the side on which the tonsil appears to be most involved.

Pus may be reached and evacuated in a number of ways.

The abscess may be evacuated by way of the pharynx. After preliminary tonsillectomy a long curved hemostat is thrust at the point of greatest bulging through the superior constrictor muscle into the parapharyngeal space. Such a procedure, according to Hall, will in all probability reach only the anterior compartment of the space. A general anesthetic should not be used, for the danger of asphyxia is great. Infiltration anesthesia is risky because additional infection may be carried through the infected field into the deep tissues. It is better

Fig. 130.—1, Incision for "simple" incision. In the illustration the dotted line is somewhat long and too high; 2, incision as advocated by Mosher.

to apply cocaine locally, and in addition to obtain some blunting of sensation by anesthetizing the sphenopalatine ganglion as recommended by Guttman for the opening of peritonsillar abscesses. It is obvious that the pharyngeal approach is of limited value and is not applicable in the absence of a pharyngeal swelling; it needs to be preceded often by a preliminary tonsillectomy; frequently in the presence of a peritonsillar abscess.

The external approaches are usually favored by men of

experience. They should be used most of the time and when there is no pharyngeal lead or when the results of opening by way of the pharynx are not satisfactory after a wait of twenty-four to forty-eight hours. The "simple" external approach may be used at times with satisfaction. The angle of the mandible is found two fingerbreadths below the lobule of the ear and on a line with the mastoid tip. A vertical incision is made just behind the angle through the skin and subcutaneous tissues. A curved hemostat or scissors carried in an upward and inward direction through the deep fascia on to the internal aspect of mandible, *i. e.*, along the internal pterygoid muscle (Batson), enters the parapharyngeal space. Neither of the two above approaches permits inspection or treatment directed toward the internal jugular vein.

On the continent, especially in the Germanic countries, the approach popularized by Marschik is used almost exclusively. The skin incision is along the anterior border of the sternomastoid muscle, with its middle at the level of the angle of the mandible. The deep cervical fascia is exposed, and at the level of the angle of the jaw is incised or opened by blunt dissection in the direction of the skin incision. Further orientation depends on finding the stylohyoid muscle and the tendon of the digastric muscles. These are beneath the angle and run from above and behind downward and forward. At this point the tendon of the digastric perforates the fibers of the stylohyoid. Both muscles are retracted downward. Upward and forward blunt dissection exposes the anterior parapharyngeal space. Blunt dissection with a forceps or finger beneath the digastric carries one to the posterior parapharyngeal space and the carotid sheath. Following the stylohyoid the finger palpates the styloid process and may be carried upward to the base of the skull.

In this country, Mosher's advocacy of the submaxillary fossa approach to pus deep in the neck has made a deep impression. He recommends a generous T-shaped incision. The skin flaps are retracted and the lower border of the submaxillary gland defined. The gland lies between the two bellies of

the digastric muscle as in a sling, and is lifted upward. The facial vein is tied and cut. The finger or blunt forceps carried upward beneath the posterior belly of the digastric muscle finds the carotid sheath and pus if it is present. The styloid process is easily palpable and pus accumulations about the base of the skull may be reached. This exposure, better than the preceding one, allows for examination of the base of the tongue, and the floor of the mouth as well as the entire neck

Fig. 131.—Operative approach according to Marschik. (After Wessely.)
1, Sternomastoid muscle; 2, digastric muscle; 3, stylohyoid muscle; 4, styloglossus muscle; 5, stylopharyngeus muscle; 6, loose fascia of the pharynx.

from the base of the skull downward. The internal jugular vein is easily inspected and ligation and resection carried out. (See Fig. 130.)

Finally, the parapharyngeal space may be exposed after Kramm's recommendation by a retromandibular approach. This has the claimed advantage of exposing the parapharyngeal space from the base of the skull to the angle of the mandible, and is said to be quite easy to do. The incision is car-

ried through the skin at the anterior border of the sternomastoid muscle from the tip of the mastoid to 2 cm. below the angle of the jaw. Great care is necessary at this point to define the lower pole of the parotid gland, which is freed by blunt dissection and carried forward. Beneath and medial from the sternomastoid muscle the posterior belly of the digastric muscle now appears.

Somewhat deeper and more medial the internal jugular vein appears. One or 2 cm. in front of and somewhat medial

Fig. 132.—Dissection of parotid region. (After Tandler.) In the exposure as advocated by Kramm, the lower and posterior border of the parotid gland is dissected free and pulled upward and forward.

to the vein the styloid process is opened by blunt dissection and the process cleared from its tip upward as high as possible.

A small or medium-sized nasal speculum is passed into the prepared cavity with blades closed. When the speculum is opened the styloid muscles separate, the styloglossus anteriorly, the stylohyoid posteriorly, and the whole anterior parapharyngeal space is exposed. Further use of the speculum exposes the vascular sheath back of the styloid process.

The advantage of this exposure is that it brings one to the

center of the infected area. The greatest difficulty is encountered at first in freeing the lower pole of the parotid gland. Thereafter the dissection proceeds with ease. The styloid process, a most important landmark in these exposures, is easily exposed and no large vessels are in the way excepting the internal jugular vein which one is anxious to see and handle surgically, if necessary.

CLINIC OF DR. CLARENCE F. G. BROWN

NORTHWESTERN UNIVERSITY MEDICAL SCHOOL AND
ST. LUKE'S HOSPITAL

JAUNDICE: A BRIEF DISCUSSION OF DIAGNOSIS FOLLOWED BY A PROPOSED MEDICAL MANAGEMENT

THE principal decision which a physician should hasten to make when he sees a patient with jaundice is whether to advise surgery or try medical management. It is just as important in this year of progress and laboratory enlightenment to elicit a most detailed and careful history as it ever was before. The interpretation of the many tests to measure liver function still depends on the clinical conditions as shown by the history, the physical examination, roentgen studies, and the usual laboratory procedures. If surgical measures are finally chosen, it is usually our experience that patients seem instinctively to refuse or defer an operation in painless jaundice. This patient deferred several times. Medical management must be advised not only to help the condition if it can be helped, but to uncover latent symptoms so that the conditions difficult to diagnose, primary carcinoma of the bile tract, carcinoma of the head of the pancreas, and silent stone, will not be allowed to develop past the point of helpful surgery.

The patient I am showing you today illustrates the necessity of briefly reviewing the increasing physiologic knowledge of the liver and bile tracts so that we may benefit by better clinical judgment. Today we can bring out only an occasional point so completely discussed by Ivy¹ in his recent review with a bibliography of 553 articles covered. Each year, through advances in the fact-finding sciences of physiology and pathology, we are able either to *discard* or justify our remaining clinical concepts.

The decision as to policy of treatment which we faced in this patient is a common dilemma. Even with our better understanding of liver processes it is still difficult to be correct in the choice of either medical or surgical treatment of jaundice. To illustrate these points in differential diagnosis I will tell the story of C. S.

This strongly built, well-nourished man, fifty years of age, came to our clinic in February, 1933. He was deeply jaundiced, had no pain, not very sick, and complained only of some fatigue, belching and constipation. He remembered having a painful jaundice five years before which cleared up in a few weeks without surgical aid. As he recalled his sensations in the previous attack, he did not seem much impressed by the pain but always pointed to the right costal margin. He did not recall radiation to the shoulder blade. It was definite that the first attack under our observation was at least less painful as he senses only an epigastric fullness. He stated that he lost 40 pounds during seven weeks. In December, 1932 he lost his appetite. Following this, the jaundice began with a slow insidious onset. He was never seriously ill nor had he ever noted any gastro-intestinal symptoms except for his 1928 jaundice. He had been in perfect health from 1928 to December, 1932. There was nothing in his habits or occupation to suggest contact with carbon tetrachloride, chloroform, tribromethanol, phenylhydrazine, phosphorus, or trinitrotoluene. He was a machinist, never drank alcoholic beverages; not even coffee. He went to bed early, had a happy home life with good cooking and never worried. As he never took any kind of medicine we could rule out the other toxic jaundices due to the cinchophens and arsphenamines. He had eaten few carrots and no mushrooms. Some of the above conditions have been discussed by C. A. Elliott¹ and Walter Nadler,² Starr,³ Bloch and Rosenberg⁴ and Carroll,⁵ which form a good background for clinical understanding of the liver and bile tracts.

Physical examination showed no fever or enlargement of the spleen. There was no history of intermittent fever with chills as with a "ball valve" stone in the common duct. He did not have the greenish-yellow color as in Gaucher's disease and the normal spleen definitely ruled that out. A negative Wassermann test turned our minds from a luetic cause of jaundice. A coincident Banti's disease was ruled out by the absence of spleen enlargement and hypochromic anemia. There were no other signs of decompensation to go with the jaundice associated with a failing heart. There were no enlarged collateral veins visible beneath the skin of the abdomen and not enough enlargement of the liver to suggest cirrhosis. The liver edge was smooth, enlarged three fingers and very faintly tender. There were no hard nodules and not enough enlargement of the liver to suggest the jaundice from a liver so full of metastases as to bring on jaundice. This condition is usually quite terminal and easy to diagnose by a careful search. The gallbladder could be palpated and was not tender. With no fever it is hard to conceive of yellow fever. I have seen a patient with undulant fever who had coincident mild jaundice but again we can rule this out.

The usual blood studies ruled out the jaundice with pernicious anemia, sickle cell anemia and very probably hemolytic jaundice. The patient had never noted blood in the urine and our tests showed none so that paroxysmal hemoglobinuria could be ruled out. Malaria was not found and there were no symptoms or history suggestive of "blackwater fever." The liver did not seem large enough to consider this a typical example of Hanot's cirrhosis. Apparently obstructive back pressure must either be quite marked or of a long duration or occur in a vulnerable liver to produce this old clinical picture. In Weil's disease there is usually fever, albuminuria and more malaise and aches than this patient had. After considering this array of clinical disorders together with a few not mentioned, such as Laennec's cirrhosis and Hodgkin's disease, I think you will agree in a movement toward pure pathology and physiology to simplify such a subject as this.

There are several diseases not yet ruled out even with the complete gastrointestinal roentgen study. These are aneurysms of the hepatic artery, dormant echinococcus cyst and peritoneal adhesions. Primary tumors of the gallbladder or bile tracts or the pancreas are consistently missed by the best roentgenologists. Gallbladder visualizations are risky procedures in jaundice. One was done on this patient largely for academic purposes after the jaundice had subsided somewhat. No stones were seen, the gallbladder partially filled and was very slow in emptying.

Surgery was advised because of a provisional diagnosis of possible carcinoma, although the history would indicate a silent stone with partial obstruction and secondary hepatitis. The patient decided to assume the risk of deferring the operation, which gave us the opportunity of using the usual liver function tests. Time does not allow the interpretation of each one during the course of observation from February, 1933 to May, 1935. During each of the three attacks which occurred, the urine was dark, the stools light. The gastric contents were examined frequently for the two-year period and showed a free acid of 40 to 60 at first, gradually falling to 30 to 40, since August, 1933. During the first three weeks after each attack the benzidine test was positive in the stomach contents and stools and at other times was negative.

Recently there has been an increasing interest in liver function tests accompanied by a widespread increase in their uses. These tests are certainly an effort in the right direction. Many times they are ordered by a busy physician as part of his ritual, in much the same way as useless metabolic rates. They may be blamed afterward for a bad decision which should have been based on more simple and obvious observations. As it turned out later in this instance they, together with the time elements, helped guide us to a better pre-operative diagnosis than the provisional one of carcinoma. Some of them require a highly trained laboratory staff and some are so complex as to lead to error. The interpretation

is extremely confusing in a mixture of pathological conditions, such as slight obstruction with moderate hepatitis.

The icterus index is quite simple and measures the yellow color of blood serum in units as compared to a 1:10,000 potassium bichromate solution. It is more satisfactory than skin color which changes shade slowly. It will show an increase in jaundice when urine does not always reflect the change. The abnormal readings begin at about 15 and are said to go over 300. It is difficult for us to make what we consider accurate readings over 200. This patient's maximums were 130, 80 and 160 in the three attacks. If it changes rapidly, we may allow ourselves to think of a changing obstructive process.

The van den Bergh reaction was taken up in this country soon after the World War. The apex of exact interpretation in the effort to differentiate medical from surgical jaundice was reached about 1929 to 1932. We have come more and more to use the results of this test cautiously. In obstruction the rise from a normal reading of 1 to 3 mg. rapidly rises to 15 to 30. In silent stone this does not differentiate from obstruction by neoplasm. In obstruction the immediate direct van den Bergh was supposed to be positive; the indirect positive. A delayed direct reaction was interpreted as reflecting a hemolytic form of jaundice. Where both obstructive and nonobstructive forces were supposed to be taking place simultaneously, as in toxic and infective jaundice, the biphasic reaction should occur. Jaffé's conception of so-called catarrhal jaundice being primarily a hepatitis which we believe is correct, makes such interpretations most complicated and unsound. I believe until we know more, the practitioner should use more simple criteria. In most instances the intra-hepatic damage has already begun to give the delayed direct reaction by the time the doctor is able to see the patient and make the test. Our patient showed 16, 5 and 18 in the three attacks. When considered together with the icterus index, we would think perhaps that the first attack was approximately 60 per cent obstruction and 40 per cent hepatitis, the second

largely hepatitis, and the last mostly obstruction with some hepatitis. As it happened this man was about correct, but such interpretations might just as well have led us astray unless we carefully questioned and examined the patient. N. C. Gilbert has tried injecting bilirubin 1 mg. per kilo into patients to study the degree of liver embarrassment. Bilirubin is very expensive and we consider this only as a "research step" in liver studies. We did not make this study in this particular case, although it should have been done.

The bromsulphalein test as described by Serby and Bloch⁶ may be of use in the diagnosis of carcinoma of the head of the pancreas.

The blood cholesterol determinations are of some interest to those of you having technicians who make no errors. This is especially true when cholesterol esters are studied. When the liver is embarrassed the cholesterol usually removed by the liver is found increased in the blood stream. In obstruction the cholesterol goes up rapidly from the normal level of 180-200 to as much as 500 mg. If at the same time the cholesterol esters decrease disproportionately, *i. e.*, more than their 40 per cent drop to 20 per cent or less, it makes us suspect that intrahepatic damage is increasing in proportion to the obstructive process. This is clearly described by Ottenberg.⁷

The galactose tolerance test depends on measuring the loss of efficiency of the liver as a factor in carbohydrate metabolism. After 40 Gm. of galactose is given under basal metabolic conditions about 3 Gm. or less comes out in the urine in five hours. If more is excreted, we may conclude that at least something is deficient in carbohydrate metabolism; perhaps the liver. This would not help us in choosing either medical or surgical management of jaundice, but it has a distinct place in metabolism clinics to further knowledge.

This patient was jaundiced for seventeen weeks in his first attack in the winter and spring of 1933. This persisted in spite of the medical management to be described later. He cleared up, felt well from June, 1933 to July, 1934. He was very conscientious in his clinic visits for gastric and stool

analyses during the entire interim. He followed his diet most of the time. In July, 1934 the weather was very hot and jaundice recurred (the second attack referred to in discussion of liver function tests). This attack lasted only three weeks and was probably just a simple hepatitis with little obstruction as hinted by the icterus index and van den Bergh. All went well with him until he contracted an influenzal attack in January, 1935. He continued his work and felt very bad for a month, at which time he slowly redeveloped his jaundice. In February, 1935 he had more epigastric heaviness, but no actual pain. Thus the history of influenza suggested that hepatitis was the strongest factor, but the liver function tests pointed more to obstruction.

The many tests he had undergone were again explained to him and a third invitation for surgery was presented him. A note in the record at this time reads: "If there is a neoplasm it is not a fast growing one." The diagnosis became partial obstruction of the common duct with recurring hepatitis. The patient consented and operation in March, 1935 disclosed a small stone partially obstructing the ampulla of Vater with probable mild hepatitis. The surgeon thought it inadvisable to remove a section of liver for study. There were a few very small stones in a large thickened gallbladder. The stomach and duodenum seemed normal to Dr. H. E. Jones, who performed the operation. Cholecystectomy was performed and the patient made a good recovery and has felt well since.

We may conclude from this that a hepatitis or so-called catarrhal jaundice was secondary to a partial obstruction. The liver vulnerability was probably caused by a residual infection following the first obstruction in 1928; or the partial obstruction off and on since. Difficulties arose when the patient became fatigued; during hot weather, after cold infection, or after dietary indiscretions.

At the time this patient came to the clinic in 1933 we were on our ninth year in trying a new type of management for embarrassed livers and low-grade gallbladder inflammations

with or without stones. It may be briefly described in three stages and should be used only when medical management seems advisable after careful study.

In the presence of jaundice we follow conventional lines of absolute rest, plenty of fluids, excess carbohydrates, intravenous glucose, and rarely intravenous calcium gluconate. We are sparing in the protein allowance and begin a bland creamy diet described later as the jaundice subsides. Decholin or Epsom salts are not given in an active jaundice.

When the jaundice has subsided the first stage of management for all low-grade gallbladder disorders and liver dyscrasias is gradually begun. This is virtually a strict hourly feeding ulcer management including the usual cream, eggs, cereals, custards, gelatins and butter with three pureed cooked vegetables and two pureed cooked dried fruits. If there is pain, refer to surgery. The calories are gradually increased according to the patient's tolerance to about 3000 daily. Most authorities do not believe that the bile tract empties, such as cream, butter and eggs, should be used. This clinical management follows Ivy's and Jones' idea that overcoming stasis without quite overloading the embarrassed liver's ability may help rehabilitation toward its natural physiologic function. From our studies we believe the stomach outlet is usually in difficulty at such a time and should be protected by the small, frequent, neutralizing feedings. Remember the positive ben-zidine tests in the gastric contents for the first few weeks of each attack in this patient. Antispasmodics, such as tincture of belladonna, with phenobarbital are used routinely.

The second stage of management is withheld until the patient has nearly recovered and occult blood has been absent from the stools and stomach for some time. This is the addition of trial teaspoonful doses of Epsom salt or $\frac{1}{2}$ teaspoonful doses of magnesium oxide replacing feedings at the estimated emptying time of the stomach. The patient should never be purged, and the amount should be cut down if more than one or two bowel movements per day result. If no pain, continue the first stage of medical management. If pain results, refer

the patient to surgery. This stage is as much diagnostic as therapeutic and answers the requirements for a management which will bring out latent symptoms.

The third stage is used only after the jaundice has gone and the patient reverts to the chronic bile tract and liver dyscrasia classification. This is the addition of decholin to the first stage treatment. According to K. K. Jones, this markedly increases bile flow in dogs. If there is pain, refer to surgery; if not, either continue on stage one or stage three.

Some of the most interesting findings in this management have been the gratifying results on the gallbladder dyscrasias of which there are a surprising number. These usually occur without jaundice. Psychic management with antispasmodics stronger than usual are of great assistance to the patients.

The interrelation of diseases of the liver and bile tracts to duodenal disorder cannot be overemphasized. We should seek always to protect stomach and duodenal lining in any treatment for jaundice or associated disorders. We should give every possible aid to smooth natural bowel peristalsis by avoiding any cathartics (except for diagnosis). The pureed cooked vegetable and dried fruits plus mucilose or metamucil can do a great deal in avoiding spasm of the bile tracts. This avoids back pressure and stasis which probably helps in the rehabilitation of inflamed liver cells and bile passages.

CLINIC OF DR. JEROME HEAD

NORTHWESTERN UNIVERSITY SCHOOL OF MEDICINE

THE TREATMENT OF BRONCHIECTASIS

DILATATION of the bronchi was first called to the attention of Laennec by his pupil Cayol. In 1819, in the first edition of "*Traité sur l'auscultation médiate*" Laennec spoke of it as an extremely rare disease. By 1826 he had become impressed with its frequency. From that time until the present, as attention has been drawn to it and diagnostic methods have been developed, there has been a progressive recognition of its true incidence. Today it is known to stand second only to tuberculosis as a cause of chronic cough. In some hospitals it has been found in 7 per cent of all autopsies. It is probable that in this present gathering of 50 people there are 3 or 4 affected with it and I am certain that one rarely lectures on the disease to a class of medical students without having one or more come up afterward and say that they have the symptoms described.

Bronchiectasis varies greatly in the severity of the symptoms which it produces. Fortunately many cases are mild and those so afflicted lead long and active lives scarcely incommoded by their slight morning cough and expectoration. In its severer form, and the severity of the symptoms seems to bear little relation to the size of the dilatations, it is a terrible and distressing affliction, the frequent coughing spells, the foul breath and the necessity of expectorating great quantities of fetid sputum rendering the subject a social outcast. While fever, emaciation and systemic symptoms are extremely rare and most patients, even those with profuse expectorations,

appear to be in good health, the disease does threaten and shorten life. In a series of 200 cases which I studied, 50 per cent began before the tenth year, but of those over forty years old few or none dated the onset to childhood. This suggests that most of those affected in childhood succumbed to pneumonia, lung abscess, brain abscess or some of the other complications of the disease before reaching forty.

Bronchiectasis is one of the most difficult diseases to treat. Success is usually partial and often slight. The dilatations are permanent deformities which can be cured only by excision of the lung, and the chronic bronchitis is usually extremely resistant. While any one of a variety of remedies may give startling results in an occasional instance, too often all remedies fail. Today I wish to speak particularly of the treatment.

Sydenham wrote: "I have come to this conviction—that those who have directed their eyes and their minds the most accurately and diligently to the phenomena of disease will excel in eliciting and applying the true indications of cure." Having in mind this practical attitude toward clinical observations, I wish today, while speaking of bronchiectasis, to concern myself not with the dilated bronchi or their forms or causes, but with the chronic bronchitis to which they predispose. Dilated bronchi neither produce symptoms, impair health nor threaten life. They do favor the establishment of chronic infection and it is this that is the true disease. Since it is the bronchitis which must be treated, a consideration of its pathogenesis—the factors which favor its inception and determine its chronicity—should point the way to logical and successful treatment.

In all of the body cavities and tracts there are four conditions which incite infection and maintain it in a chronic state. These are:

1. Interference with the normal evacuation of secretions.
2. Persistent reinfection.
3. The presence of a foreign body.
4. Infection with tubercle bacilli or other resistant organisms.

In bronchiectasis the normal mechanisms for evacuation of secretions, the ciliary action of the epithelium and the peristaltic contractions of the bronchial musculature, are destroyed. These being out of function, gravity favors the accumulation and stagnation of secretions and the development of chronic infection. The rôle of gravity is of the greatest importance. Bronchiectasis is rare in any part of the lungs save the posterior and most dependent portions of the lower lobes. When it does occur in the upper lobes the etiology is either parenchymal fibrosis or bronchial obstruction and upper lobe dilatations are rarely complicated by chronic bronchitis or profuse secretion. These facts justify one in surmising that bronchiectasis, usually in its etiology, and practically always in its clinical manifestations, is a disease of posture—one of the many untoward results of man's assumption of the unnatural erect and supine positions. Whether or not gravity so hinders evacuation as to produce the dilatations or the diseases which produce them, it is certain that once the bronchi are dilated and the ciliary and peristaltic mechanisms compromised, gravity is the chief cause of the accumulation of secretions and the persistence of infection.

Persistent reinfection sometimes causes bronchiectasis and practically always plays a part in maintaining the infection. Chronic sinusitis is recognized as a cause of the disease and in nearly every case of bronchiectasis the sinuses are involved. In some instances they are the etiological factor and in others are secondarily infected from the continual spraying of the upper respiratory passages with the raised secretions. In all cases the chronic postnasal discharge adds constantly to the infection in the dilated tubes.

Foreign bodies, either of extraneous origin or broncholiths formed in situ, are not uncommon in bronchiectasis. When present, they are an important cause of profuse bronchial secretion.

Tubercle bacilli and other resistant organisms are probably not a factor in the chronic bronchitis of bronchiectasis. While the condition often complicates tuberculosis, chronic

bronchial infection with mixed organisms or parenchymal fibrosis probably produce it. It has been suggested that infection of the bronchial walls by fusiform bacilli and spirochetes causes the dilatations. Whatever may be the truth of this, once the dilatations are established, stagnant secretions in which develop any and all varieties of organisms cause the bronchitis and expectoration.

From these considerations of pathogenesis the following measures should be of value in clearing up the bronchitis of bronchiectasis:

1. The prevention of stagnation of secretions by postural drainage, induced cough, bronchoscopic aspirations and bronchial lavage.
2. The prevention of reinfection by cleaning up infection in the upper respiratory tract.
3. Search for and removal of foreign bodies or dilatation of bronchial stenoses.
4. Medication, either local or internal.

Concerning this last, I have had most success with extremely large doses of potassium iodide. In an occasional case the results have been striking. Stokes and the older clinicians favored tartar emetic. Repeated instillations of iodized oil have been strongly recommended by Ochsner and others. Good results are rare and it is probable that they are due to the systemic rather than the local action of the drug.

Many patients are better during the summer months, some entirely free from symptoms. Such cases are apt, but not certain, to be benefited by residence in a dry, warm climate. It is my belief that relief comes less from the quality of the air than from the avoidance of acute upper respiratory infections which are less common in equable climates. One patient of mine was practically symptom free during a winter he spent in a small isolated village in Alaska. No one should be told to change his residence because of bronchiectasis until he has first demonstrated that he will gain the relief he seeks.

Surgery is assuming a more and more important rôle in the treatment of bronchiectasis. Surgical removal of the

affected lobe or lobes is the only ideal measure. Until recently the mortality from the operation was so high as almost to preclude its use. Within recent years improvements in technic have so lowered this that in skilled hands it is no longer prohibitive. It is probable that eventually the operation will become relatively safe. Tudor Edwards has reported a series of 48 lobectomies with a mortality of 8 per cent. At the best there will always be many cases in which it cannot or need not be used.

In unilateral cases phrenicectomy usually produces an appreciable reduction in the cough and sputum and occasionally a symptomatic cure. Why it does this is uncertain. Graham has produced theoretical and experimental arguments tending to prove that paralysis of the diaphragm hinders rather than favors drainage of the dilatations. He cites instances in which the operation seems to have brought on pneumonia and gangrene. In approximately 50 cases, I have not observed this and have had results which lead me to continue using the operation. Recently I have been blocking the nerve and later extracting it if the observed improvement warranted.

Thoracoplasty has been tried and generally abandoned. The cautery lobectomy of Graham has not given good results.

I have chosen 3 cases to present which are unusual enough to warrant consideration and which illustrate certain of the points which I have made concerning the etiology and treatment of the disease.

The first is a case of dry hemoptotic bronchiectasis. This type is of particular interest because it demonstrates that dilatation of the bronchi even in the lower lobes may exist without being complicated by bronchitis and may produce no symptoms. It is also important because it emphasizes the fact that bronchiectasis is a common cause of hemoptysis.

Case I.—Montgomery Ward Medical Clinic of Northwestern University, No. 48,425. Mr. J. P., nineteen years old, first came to the clinic in March, 1932 complaining of coughing and expectorating blood.

His past and family histories were essentially negative. Close questioning failed to reveal any past illness which might have produced dilatation of the bronchi.

His present illness started two years before with a sudden onset of profuse and repeated hemoptyses. He was sent to Edward Sanatorium where Dr. George Dyche made the diagnosis of bronchiectasis and verified it by bronchography. He had remained in the sanatorium four months without further bleeding and had then returned to work. His cough disappeared entirely and he remained free from symptoms until two weeks before coming to the clinic. At this time his hemoptysis recurred and had been repeated frequently during the past few days.

Fig. 134.

Fig. 135.

Fig. 134.—Case I. Dry, hemoptysic bronchiectasis of right lower and middle lobes before injection of iodized oil.

Fig. 135.—Case I. After injection of iodized oil.

Physical examination showed nothing abnormal save decreased breath sounds and occasional coarse bronchial râles at the right base and in the axilla.

x-Rays taken after the injection of iodized oil showed cylindrical dilations of the bronchi in the right middle and lower lobes (Figs. 134 and 135).

On March 18, 1932 the right phrenic nerve was extracted.

Since that time the patient has had no further hemoptyses, but within the past year has developed a slight morning cough. He expectorates about $\frac{1}{2}$ ounce of sputum each twenty-four hours.

Case II.—Extensive saccular bronchiectasis of left lower lobe in boy fourteen years old, secondary to foreign body in nose since childhood. Marked improvement following removal of foreign body, phrenicectomy and postural drainage.

E. M., Montgomery Ward Medical Clinic of Northwestern University, No. 45,492. This boy was fourteen years old when he first came to the clinic in January, 1931. He complained of a chronic productive cough, pain in the chest, hemoptysis and nasal obstruction.

His father had pulmonary tuberculosis.

His mother and 3 sisters and 2 brothers were living and well.

He had measles and whooping cough in early childhood and many acute respiratory infections.

The present illness dated back to infancy. The father said that the boy had always coughed and had a nasal discharge, and has had repeated attacks of pneumonia. For years he had coughed a great deal, severe attacks occurring in the morning and whenever he exerted himself in play. At these times

Fig. 136.

Fig. 137.

Fig. 136.—Case II. Severe bronchiectasis of right lower lobe secondary to foreign body in nostril.

Fig. 137.—Case II. After injection of iodized oil.

he raised large quantities of fetid sputum. His father estimated that he expectorated more than a cupful a day. Slight hemoptyses were common as were also pains in the left chest. Physical examination at that time showed a poorly developed and nourished boy with profuse nasal discharge and frequent loose cough. His complexion was sallow and his attitude listless.

Physical examination showed moderate clubbing of the fingers and dulness, decreased breath sounds and coarse bronchial râles over the lower half of the left lung.

For the x-ray findings see Figs. 136 and 137. x-Rays of the sinuses showed normal aeration.

The patient was given potassium iodide and instructed in postural drainage. The left phrenic nerve was extracted.

He was referred to Dr. O. H. Maclay of the ear, nose and throat depart-

ment, who found a markedly deviated septum, obstruction of the right nostril and mucopus in both sides. A diagnosis of deviated septum with possible foreign body was made.

At operation Dr. Maclay found a metal screw firmly embedded in scar and granulation tissue in the right nostril. The septum was straightened and the tonsils and adenoids removed.

Following these operations improvement was rapid. His cough and sputum decreased markedly and his gain in weight and general health was striking. For the past four years he has coughed only on rising in the morning and has raised less than 1 ounce of sputum each twenty-four hours. Today at the age of eighteen he is a well-developed and alert young man.

In this case it seems certain that the foreign body in the nose and the consequent nasal infection caused the bronchiectasis. That is was important in maintaining the infection in the dilated tubes is evidenced by the prompt improvement following its removal. Much elevation of the diaphragm was prevented by adhesions and it is doubtful if this operation contributed greatly to the result.

Case III.—Severe bronchiectasis of left lower lobe; constant fever; repeated hemoptysis; treatment by medication, postural drainage, phrenicectomy and paraffin pack ineffective; cure following lobectomy.

Miss M. D., Montgomery Ward Medical Clinic of Northwestern University, No. 43,734. This patient, a girl seventeen years old, first came to the clinic in

Fig. 138.

Fig. 139.

Fig. 138.—Case III. Bronchiectasis of left lower lobe before injection of iodized oil. Severe and disabling symptoms.

Fig. 139.—Case III. After injection of iodized oil.

September, 1931. She complained of a chronic cough with profuse expectoration of two years' duration. The onset of her cough was gradual and there was nothing in the family or past histories which could account for it. At the time that it developed she was working in a nut factory shelling nuts, a fact which suggests that a foreign body may have been inhaled. She was raising approximately 4 ounces of fetid sputum each twenty-four hours. Hemoptyses were frequent and fever was present much of the time.

Physical examination revealed a poorly developed and nourished young girl. There were no abnormal physical findings in the lungs.

The x-ray findings are shown in Figs. 138-140.

Fig. 140.—Case III. Following lobectomy. Shadows in right lung field are artefacts.

Postural drainage, phrenicectomy, and medication with potassium iodide were ineffective in improving her condition. She grew gradually worse. Her sinuses which had been normal on admission became infected. In August, 1932 a paraffin pack was inserted over the base of the left lung. This gave no relief.

In November, 1933 the paraffin pack was removed and the left lower lobe resected. Since that time she has gained 12 pounds in weight. Her general health has improved markedly. She still coughs and raises some sputum but has no fever and no hemoptyses. The operation has changed her from a chronic complaining invalid to a healthy and ambitious young woman.

This case is important as demonstrating the severe and disabling type of bronchiectasis. Any procedure, however radical, which offered a possibility of cure was justified. It is of interest that the sinuses became infected three years after the onset of the cough while the patient was under observation.

One could say much more about the details of the treatment. I would say in general that it should be intensive and radical only in proportion to the severity of the symptoms and that in the majority of cases one must be satisfied with partial results. As the mortality of lobectomy is reduced, and I feel certain that it will be, its indications in unilateral cases can be accordingly extended.

In closing I would like to emphasize the importance of cleaning up infections in the upper respiratory tract and the necessity, if this is to be accomplished, of close cooperation with the specialist in diseases of the nose. In our department we had little success from this form of treatment until all of our cases were referred to a single man. Dr. Otis H. MacLay, by frequent consultation with us, has come to understand the problem from our point of view and by so doing has been able to adjust his measures to the requirements of the particular case and to render us invaluable service.

CLINIC OF DR. VINCENT J. O'CONOR

WASHINGTON BOULEVARD HOSPITAL

THERAPEUTIC VALUE OF PROSTATIC MASSAGE: WITH A DISCUSSION ON PROSTATITIS AND THE SIGNIFI- CANCE OF PROPER RECTAL PALPATION OF THE PROSTATE GLAND

For discussion this morning I wish to present this patient and give a brief history of his complaint.

A. G., aged thirty-six, came to the hospital complaining of persistent low backache, loss of energy and appetite. He is an unmarried clerk of sedentary habits who has always been well except for occasional sore throats and head colds each winter. He had had measles and scarlet fever in childhood and influenza in 1918. He denies gonorrhea or other urinary infection. He first consulted a physician for sacral pain two years ago. At this time an x-ray was made and the patient was told that he had a "slipped sacro-iliac joint." Orthopedic belts and medicine by mouth did not improve the condition. Several months later he consulted an osteopath who told him he had a "slipped vertebra" but manipulative treatments by him brought no relief. The patient has since taken frequent doses of aspirin and other sedatives with temporary relief. More recently the sacral and lower lumbar pain has been bilateral and when he tries to rise from bed in the morning the effort is most painful. During the day the pain becomes less severe and is often almost entirely absent on retiring at night. Exercise, which he has to force upon himself, does not increase the pain. Other than the above, the pain is not related to bowel movements, urination or any other function. He has very occasional sexual intercourse and thinks the pain is lessened for several days after these experiences.

Physical examination reveals a well-nourished man apparently in good health. The teeth are in good condition, the tonsils appear to be the seat of chronic infection. Heart, lungs, blood pressure and blood count are normal. Urinalysis is negative except for a slight excess of leukocytes (10-15 per high-power field after centrifuging) in the sediment. Mobility of the spine is normal; there are no areas of tenderness along the vertebrae or over the sacrum. x-Rays of the teeth and spine show no abnormality. Rectal examination reveals a normal sphincter, no anal fissure or hemorrhoids and a smooth rectal mucosa. The prostate is twice normal size, soft and boggy without any indurations or infiltrations in the prostatic tissue. The rectal mucosa is

freely movable. Both seminal vesicles are palpable and distended with a somewhat ropy consistency on outline. Thorough massage and stripping of the prostate and vesicles is followed by a rapid flow of material at the external urinary meatus and this fluid on cover slip examination under the high-power field of the microscope shows 75 to 100 pus cells per field and many clumps. Cultures and smears of the prostatic secretion show mixed staphylococci and colon bacilli. The day following the diagnostic massage the patient stated that for the first time in two years he had no pain in his back when he awakened in the morning. Our diagnosis in this case is chronic prostatitis of

Fig. 141.

nonspecific origin, probably secondary to chronic tonsillitis. The therapeutic procedure will include removal of the tonsils and prostatic massage at five-day intervals until the expressed material yields less than 10 pus cells per high-power field and, of course, until all symptoms are completely relieved.

Discussion.—This patient's history illustrates the necessity for a thorough rectal examination of the prostate in every male complaining of backache. Unfortunately the average

physician does not include a routine rectal examination in searching for the cause of complaint in these individuals. This is an omission of which I hope you gentlemen will not be guilty. It is not necessary to be a genito-urinary specialist to make a competent examination of the prostate. The most effective examination may be made with the patient standing on a low stool or platform, the body bent over a table, toes turned in, knees slightly bent, back swayed. If the patient is bedridden, he should be examined lying upon his side with his knees drawn up. The prostate, seminal vesicles, the base of the bladder and the lower end of the ureter may be felt by the examining finger in the rectum. The finger is best protected by a rubber finger cot, using a new one for each examination. A gauze or paper shield for the hand is also discarded after the examination.

Normally the prostate as felt per rectum is heart shaped with its apex toward the anal sphincter, its base more or less notched in the center, the lateral lobes quite elastic, its central groove between the two lobes more or less marked. Normally the prostate does not project into the rectum and the lateral lobes are flat rather than bulging. Careful examination consists in sweeping the tip and flexor surface of the index finger over the surface of the gland and around its borders. All students and physicians should avail themselves of the opportunity to make frequent rectal examinations so that they may learn to differentiate minor or gross changes from the normal.

The lobes of a normal prostate are flat, flaccid and only moderately sensitive. There are no indurations or variations in consistency in the texture of the unaffected gland. Discrete hard masses felt between the rectal mucosa and the prostate proper are usually lymph nodes or phleboliths. Diffuse thickenings within the lateral lobes or projecting toward the seminal vesicles are usually of an old inflammatory nature. Carcinoma most commonly begins in the posterior lobe and the rectal mucosa becomes fixed to the gland which itself becomes immovable. Hard boardlike areas replace the normal prostatic tissue with discrete nodules of cancer to be felt in place

of the smooth, uniform normal consistency. Acute inflammations give the feeling of a tense, hot, swollen gland projecting rectally in an abnormal manner. When abscess occurs in the substance of the gland, an area of softness or fluctuation may be felt. In adenomatous hypertrophy the gland may bulge markedly into the rectum and the lateral lobes, if large, obliterate the median groove, giving one the feeling of a large, smooth, symmetrical tumor.

Prostatic Massage.—Prostatic massage first came into popular use in Stockholm in 1894, although several references were made in Germany concerning the cure of chronic prostatitis by repeated digital expression in 1893. The technic most popular with genito-urinary surgeons is as follows:

The patient presents himself with a bladder well filled with urine and he assumes the position previously described. The protected index finger is inserted within the rectum and gentle to firm pressure made first over one lobe and then over the other with a stroking around and downward movement directed toward the openings of the prostatic ducts in the deep urethra. Finally the finger is drawn from above downward over the posterior urethra so as to express secretions from the sinus pocularis and urethral openings of the ejaculatory ducts. This manipulation should be continued for from one to three minutes. Mild massage may be indicated twice weekly; vigorous massage not more often than once a week. The therapeutic benefit derived from digital expression of the prostatic and vesicular content combines the expression of secretion and resultant improved drainage through normal channels, the stimulation of circulation in the region of the prostate proper and increased absorption from infected areas brought about by the above reactions. Rough or too vigorous massage, especially in the presence of acute infection, may force infected material down the lumen of the vas and cause epididymitis.

Prostatic massage is a useful measure in chronic catarrhal prostatitis, in chronic fibrotic prostatitis and in atrophic or atonic conditions of the prostate. It is of no value or is contra-

indicated in acute infections of the prostate, in tuberculosis, neoplasm or hypertrophy. The intelligent treatment of non-gonorrheal prostatitis must include the removal of systemic foci of infection, such as abscessed teeth, infected tonsils, nasal sinusitis, etc. Stricture of the urethra, when associated, must be treated by progressive dilatation of the urethra, but preferably at an interval of two to three days between prostatic manipulations. Rectal insuffusion of heat, systemic stimulation of immunity, proper hygienic advice, and urinary antiseptics may be combined to good advantage with regular prostatic massage in the treatment of chronic prostatitis.

CLINIC OF DR. RICHARD J. TIVNEN

MERCY HOSPITAL

THE VALUE OF EYE SYMPTOMS IN THE DIAGNOSIS OF GENERAL DISEASE

Preliminary.—The physician's greatest problem is diagnosis. His chief reliance in establishing it is the symptoms the patient presents. It is exceptional for one symptom alone—the so-called pathognomonic symptom—to determine a diagnosis. Practically always one must depend upon a group of symptoms in reaching a conclusion. Clinical experience demonstrates that the largest yield of diagnostic data results when one adopts as a routine in every case a comprehensive plan of procedure, which interrogates, so to speak, every organ or structure, which offers a possibility of contributing to the diagnostic problem. The value of eye symptoms in the diagnosis of general disease is of interest in this connection.

Eye symptomatology is of frequent aid, not alone in diagnosis of general disease, but is often also of great value in the *early* diagnosis and prognosis, notably in such general conditions as Bright's disease, brain tumor, arteriosclerosis, diabetes, and endocrine disturbances. A field offering such a yield of diagnostic and prognostic data should not therefore remain unexplored in general examinations. It is not unusual, however, to hear of patients who have been given what is popularly referred to as a "check-up" and no investigation of the eyes has been included in this general examination. Many personal experiences might be cited demonstrating the unwisdom of such a course of procedure. I recall the case of a young child who had been given such a "check-up" by a very capable pediatrician which did not include an eye investiga-

tion. The little patient was given a clean bill of health and the alleged backward tendencies which prompted the examination were ascribed to the mother's solicitude and anxiety. A later examination of the patient's eyes disclosed the presence of congenital cataracts. Another instance of a young child whose "check-up" in which an eye investigation was omitted, resulted in the diagnosis of "gastro-intestinal disturbance;" a subsequent eye examination disclosed choked disks and the diagnosis of brain tumor.

Many reasons may be assigned in extenuation for the omission of an eye investigation as a routine in general examination. Chief among these reasons perhaps is that the usual undergraduate medical training does not ordinarily emphasize the value of eye symptoms in the diagnosis of general disease and usually but relatively little time in the medical curriculum is devoted to training in the use of the ophthalmoscope and other ophthalmologic technic. After some considerable experience in teaching in the field of ophthalmology, I hold the strong conviction that a student may with relatively little expenditure of time, training, and a negligible outlay for equipment perfect himself to a degree that he may may with confidence conduct a character of eye examination which will prove of the greatest value to his patient and of immense satisfaction to himself.

As a preliminary, it is of interest to refer to an unusual phenomenon which is associated with many eye diseases. Inflammation of body structures generally are usually manifested by pain, redness, edema, swelling, etc., and the function of the part is more or less impaired. This does not hold true for many serious eye inflammations, especially lesions of the deeper eye structures. It is quite common, for example, for a patient to be affected by such destructive eye inflammations as optic neuritis, retinitis, choroiditis and choked disk, and the external appearance of the eye be quite normal, the patient experiencing no pain whatever and his vision manifesting little or no impairment. It is a grave error, therefore, to accept either the normal appearance of the eye, the lack

of the patient's complaint of impaired vision or of pain or distress of the eye as an indication that there is no active pathology present in these deeper structures. An examination of these deeper parts with the ophthalmoscope is the only safe method of discovering this hidden pathology. It is also true that many general diseases during their course attack the eye so regularly and so consistently that the eye symptomatology of these diseases should be listed among their regular general symptomatology instead of being regarded and referred to as "complications."

It may be of interest to outline briefly the various tests and technic used in conducting an eye investigation.

EXAMINATION OF EYES

1. **Eye History.**—A special eye history should always be obtained in addition to the general history. If glasses are worn, it should be ascertained why they were ordered and the results of their use.

2. **Inspection of the Eyes.**—This is the first test made. The patient is placed in good daylight illumination and a general survey is made of his eyes. The main features to be noted are first, changes affecting the eye appendages, lids, tear channels, etc., such as edema or inflammation of lids, drooping of lids (ptosis), inability to close lids, arrangement of eyelashes, eye discharge, lacrimation, inspection of lacrimal puncta, tear ducts and lacrimal sac, eversion of lids to determine condition of conjunctiva, photophobia; next the eyeball itself—if it be reddened, its position, if prominent (exophthalmos) or sunken (enophthalmos), or if one eye deviates (strabismus, paralysis, etc.); finally testing for gross impairment of globe movements is made by holding a finger in front of patient's eyes and directing him while keeping head still to follow its movements in various directions; if binocular movement is normal both eyes should follow equally without lagging the movement of the finger in all directions; also the testing the lid movements, openings and closure, including the various lid signs detailed under Exophthalmic Goiter. The

examination of the cornea, pupils, etc., is best carried out with special tests to be referred to later.

3. **Test of Vision (Visual Acuity).**—In all tests of vision, each eye is tested separately and the eye not being tested is covered, but not pressed down. If glasses are worn, vision should be taken without and with them. Vision is tested for *distance* and for *near* (reading distance).

Test for Distance Vision.—For this purpose a large card upon which is printed letters of various sizes arranged in lines

Fig. 142.—Test of vision: Tests for distant vision—Snellen's test types.

is used, called *Snellen test types* (Fig. 142). Each line of letters is marked by a number above the line. The card is hung on the wall at a distance of 20 feet from the patient and on a level with his eyes, care being taken that the card is well illuminated. The distance of 20 feet is determined upon because rays of light emanating from objects at that distance are practically parallel and a normal eye requires no accommodation effort in bringing parallel rays to a focus; it is in a state of accommodative rest. The line marked 20 is therefore accepted as the standard of normal distant vision. If the

patient can read all the letters of this line at a distance of 20 feet, his vision is normal and it is recorded as a fraction $\frac{20}{20}$, the numerator indicating the distance the patient is from the card; the denominator the number of the line read.

Should the patient be unable to read the normal vision line—20—, he reads then the smallest line of letters he is able and the result is recorded similarly by the fraction as above. If he is unable to read the top line of letters on the chart marked 200, he is directed to approach the chart and stop when he is able to read the top line, his new distance from the chart is then estimated and if it be, for instance, 10 feet, his vision is recorded as $\frac{10}{200}$, the numerator—10—indicating the new distance he is from the card, the denominator—200—the line he is able to read. If he cannot read the top line marked 200 at any distance, he is directed to count fingers held a short distance in front of eye and the result is recorded as for example, "Counts fingers at 2 feet." Should he not be able to count fingers, his perception and projection of light is tested. This test is made in a dark room, the patient seated, an electric wall or floor light being behind him. He is directed to look directly forward and hold his eye perfectly still throughout the test. The examiner stands directly in front of the patient and with his ophthalmoscope reflects light into the patient's eyes from various angles, aiming in so doing to test the functional integrity of the center and the extremes of the retinal periphery. The patient is directed to say "now" the instant he sees the light, this indicates his *light perception*; then he is directed to reach out with his hand and touch the source of the light (the ophthalmoscope), this indicates his *light projection*. If he is wholly unable to "perceive" the light, the eye is blind. If he is able to perceive "the light" but is unable to "project" it (locate its source) accurately, this result is recorded as "perception—present; projection—poor" (or other qualifying phrase that clearly indicates the condition).

Test types are also usually marked with the metric scale, 6 meters being the equivalent of 20 feet, and $\frac{6}{6}$ being the

equivalent of $\frac{20}{20}$. Most cards also state after each line the percentage of normal vision the line represents. Where a distance of 20 feet is not available it may be obtained by the use of a mirror, the test type being placed behind the patient and the letters reflected into the mirror hung on the wall opposite the patient. There is also a visual testing apparatus on the market which enables one to test vision at any distance. When the patient is an illiterate, a card is used with the letter E placed in different positions, the patient being

Fig. 143.—Test types for illiterates. (May, "Diseases of the Eye," Courtesy of William Wood and Co.)

directed to indicate by his hand the direction of the arms of the E (Fig. 143). The symbols for recording vision may be either those of the Latin words, "*oculus dexter*" abbreviated to the symbols, O.D., or its English equivalent, R.E. (right eye) and "*oculus sinister*" abbreviated to the symbols, O.S., or its English equivalent, L.E. (left eye) or "*oculus uterque*" abbreviated to the symbols O.U., or its English equivalent, B.E. (each or both eyes). The complete formula for recording the vision should, for example, read:

*Vision*O.D. (or R.E.) $20/20$ O.S. (or L.E.) $20/40$

Test for Near Vision.—For this test a small printed card upon which is printed a series of paragraphs in different size type is used, called *Jaeger's test types* (Fig. 144). Each

No. 1.

Engaged in manual occupation of a narrow sort, the laborer has little opportunity either to try or to measure his degree of vision; his sight, when attacked by local inflammation,

No. 2.

mentary diseases or the consequences of constitutional disorders, remains good, though its acuteness lacks that extreme development

in eyesight and changes in the form, and hence in the dioptric

Fig. 144.—Test for near vision—Jaeger's test types. (May, "Diseases of the Eye," Courtesy of William Wood and Co.)

paragraph is numbered. The patient with the card held at the usual reading distance (10 to 13 inches) is directed to read the smallest type paragraph he is able to read and the result is recorded for example, as: Reading = Jaeger —No. 2.

4. Visual Field Tests for Form and Color.—A satisfactory method of disclosing gross changes in the visual form field is as follows: Patient and examiner are seated near to and exactly opposite each other. To test the patient's right

eye for a field of vision, the patient covers his left eye, the examiner his right eye; each looks directly and steadily at the other's open eye throughout the test. The examiner then extends his left arm, with fingers spread apart, to his extreme left in the horizontal plane and slowly brings the fingers inward midway between the patient and himself. The patient is directed to say "now" the instant he sees the advancing fingers. The examiner uses his own recognition of the advancing fingers to check the patient's responses; a marked discrepancy between the two is evidence of impairment of the visual field in the meridian tested, in this case the temporal field. The nasal field is similarly tested by the examiner extending his right arm and slowly advancing them to his left with fingers spread to his extreme right; likewise the upper and lower fields by alternately advancing the fingers from the extreme upward position, downward and then from the extreme downward position, upward, the directions to the patient being the same as in the first instance. The patient's left eye form field of vision is tested in the same way, the patient covering his right eye, the examiner his left. The color fields also may be tested in a similar way using small squares of colored paper suspended between the points of a writing pen. For more refined tests of the visual fields it is necessary to employ the perimeter, campimeter or the various screens.

5. Testing the Tension of the Eye.—This is quite satisfactorily done with the fingers. The patient is directed to look downward and to avoid "squeezing" the lids. The examiner then places the tips of the index finger of each hand upon the closed upper eyelid, approximately just back of the corneal periphery and gently dimples or palpates the underlying eyeball and thus obtains information of its degree of hardness or softness. The tension of the fellow eye is the standard for comparison (Fig. 145). The symbols used for recording the findings are: T= meaning tension; the letter N= meaning, normal, and the signs plus + and minus —, used as follows:

T=n = normal tension.

T+1 = appreciable hardness.

T+2 = decided hardness.

T+3 = stony hardness.

T- = diminished tension.

T-1 = appreciable softness.

T-2 = decided softness.

T-3 = very soft.

For more exact tension estimates the tonometer is used.

6. Oblique Illumination Test (Lateral or Focal).—

This test supplies information of eye structures which occupy

Fig. 145.—Testing of tension. (May, "Diseases of the Eye," Courtesy of William Wood and Co.)

the area from the cornea to the depth of the anterior portions of the vitreous, viz.—the cornea, the anterior chamber, the iris, the pupil, the lens and anterior portion of vitreous. Dilating the pupil will enable one to study more minutely the presence of iris adhesions to the anterior capsule of the lens (anterior synechiae), the lens and the forward portion of the vitreous. For more accurate examination of the lens and vitreous, however, the *direct illumination test* is necessary. The oblique illumination test requires 2 convex lenses of 2–3 inch focus; it is more convenient to use a loupe in place of

the magnifying lens. The test should be conducted in a darkened or better a dark room (Fig. 146). The light is placed approximately 18 inches to the side of and slightly in front of the patient and on a level with his eyes. The examiner adjusts the loupe to his own eyes, holds the focusing lens at its rim with the thumb and index finger, applies his little finger to the patient's face to steady it, and concentrates the light on the patient's cornea. The focusing lens should not be tilted, but its surface should be at right angles to the light. For examination of the cornea, anterior chamber and iris, pupil and anterior portion of lens, the light is concentrated

Fig. 146.—Method of oblique illumination. (deSchweinitz.)

on these structures in an oblique direction; for investigation of the central and posterior areas of the lens and forward portions of the vitreous its incidence should approximate the perpendicular. For identification of minute foreign bodies in the cornea, iris or lens or fine opacities of cornea or lens a lessened illumination or utilizing the edge of the concentrated light is more useful. The reactions of the pupil may also be investigated with this test, but they are perhaps better included in the special test of the pupils.

7. Pupil Tests.—These tests should be carried out in a dark room. They determine the pupil equality, its regularity

of outline, size and reactions. The reaction tests are three, direct light, consensual and accommodation convergence. The *direct light reaction* is made by alternately reflecting light—either with the focusing lens or the ophthalmoscope on and off the pupil and noting its response; the *consensual* reaction is tested similarly, except the reaction of the unilluminated eye is observed; the *accommodative convergence reaction* is obtained by holding the fingers in the midline close to the eyes and noting both the convergence of both eyes and the associated pupillary contractions, as the fingers are brought

Fig. 147.—Direct illumination. (Curt Adams.)

close to the eyes. The clinical value of these pupillary tests is important and they should be made as a routine in all examinations.

8. Direct Illumination Test.—This test is made by reflecting light into the eye with the ophthalmoscope used either with the aperture or any convex lens desired, held approximately a foot from the patient's eye (Fig. 147). It is used to ascertain the condition of the media—the cornea, aqueous, lens and vitreous; opacities in these appearing as black or dark spots: if the patient be requested to move the eye quickly

in various directions and suddenly halt its movement, floating opacities in the vitreous, as dark spots, will float by the illuminated pupil.

9. Ophthalmoscopic Test.—A good electric ophthalmoscope is required (Fig. 148). The direct method is satisfactory for the usual examination; it gives a magnification of 15 diameters and presents the eye structures in the upright or natural position. It is usually necessary to dilate the pupil to obtain a satisfactory view. For this purpose either cocaine—4 per cent solution or euphtalmine—2 per cent solution or homatropine—2 per cent solution is used; 2 to 3 drops of

Fig. 148.—Use of ophthalmoscope—direct method. (May, "Diseases of the Eye," Courtesy of William Wood and Co.)

solution instilled at five-minute intervals being usually sufficient, the eyes remaining closed during the period of instillation to avoid drying the cornea. The tension should always be taken before the mydriatic is used and if it is elevated a mydriatic should be omitted. Following the use of the mydriatic, as a routine, 2 or 3 drops of eserine sulphate, $\frac{1}{4}$ per cent solution, should be instilled at five-minute intervals to secure contraction of the pupil as a precaution against inaugurating a glaucoma.

Examination of the Eyegrounds.—There are four elements one must identify in examining the eyegrounds: The

optic disk (optic papilla); the *macula*; the *retinal vessels* and the *general fundus* (Fig. 148a). Obtaining simply a general or "panorama" view of the eyegrounds as a whole is not sufficient. Each of the four elements or components above mentioned must be studied individually.

The Optic Disk.—This is the first element identified, it is a "landmark," so to speak; it is the point of entrance of

Fig 148a—Normal fundus of the uniform stippled type. The papilla is oval, has sharply defined margins; is normal in color; the pigment epithelium is concentrated about the papilla and in the region of the macula. The dark, larger vessels, without distinct light streaks are the veins; the bright, narrower ones, with distinct light streaks are the arteries. (Adam Foster, "Ophthalmic Diagnosis.")

the optic nerve in the eye and hence is often referred to as the nerve head: it is also the physiological "blindspot"; the disk is located slightly nasal to the posterior pole of the eye; its form is circular or oval, pale pink in color, though this varies in degree depending upon the pigmentation of the gen-

eral fundus, is usually paler on its temporal side, its margins are well defined and two rings usually surround it—a white inner ring, the scleral, and an outer dark ring, the choroidal; on its temporal side a funnel-shaped excavation is commonly seen, the vascular funnel or physiological cup, caused by the separation of the nerve fibers, at the bottom of which may be seen the stippled gray dots of the lamina cribrosa (Fig. 149). The chief features concerning the optic disk to be noted are

Fig. 149.—Ophthalmoscopic view and longitudinal section of the disk. *a*, Central artery; *v*, central vein; *E*, physiological excavation; *s*, scleral ring; *c*, choroidal ring; *r*, retina; *ch*, choroid; *scl*, sclera. (May, "Diseases of the Eye," courtesy of William Wood and Co.)

its color, the definition of its margins, changes in its surface and its level (swollen, etc.) compared with surrounding retina.

The *macula* (*macula lutea*—yellow spot) is located approximately two disk diameters to the temporal side and a little below the horizontal meridian; it is identified as a rather oval ring, its long axis horizontal; a bright red spot at its center is the fovea centralis. Slight pathologic changes at the macula interfere seriously with vision—it therefore should be inspected with exceeding thoroughness.

The Retinal Vessels.—At the disk the central vessels, artery and vein, divide into a main upper and lower branch and these again branch into temporal and nasal branches; the arteries are smaller, redder, run a straighter course, and their light streak is more defined than the veins; the veins are larger, darker, course more tortuous, light streak not so defined as the arteries; arterial pulsation is uncommon and probably pathologic; venous pulsation especially on the disk is not infrequent and is probably not pathologic; there is no consistency in the matter of vessel crossings, a vein may cross an artery or an artery a vein; an artery, however, never crosses an artery, nor a vein, a vein. The light streak of the arteries divides the vessel into two red lines; normally the walls of the vessel itself are transparent and cannot be seen, hence the red lines observed represent the column of blood in the vessel and not its walls. The important features of the retinal vessel to be noted are, the relative size of arteries and veins, variation in their caliber, undue tortuosity, changes in their walls, interruptions in the blood current, hemorrhages along their courses, and pulsations.

The General Fundus.—The general appearance of the fundus is due to the red reflex of the vessels in the choroid and this appearance varies depending upon the amount of pigment in the choroid itself and in the retinal pigment layer. Examination of the eyegrounds of blondes, brunettes, negro, mulatto and albino will familiarize one with these varied appearances.

The above described eye tests are definitely within the scope of the general physician and may be carried out during the general examination with a relatively small expenditure of time and effort. Necessarily the interpretation and clinical application of the findings will require some further study and investigation. This may be done by consulting one of the many excellent small volumes on medical ophthalmoscopy, supplemented by practice in the use of the ophthalmoscope on the schematic eye, equipped with colored disks illustrating the normal and pathological eyegrounds.

We will now discuss more or less briefly a few diseases in which eye symptomatology is a rather frequent feature, which will serve to emphasize the diagnostic value of eye symptomatology in general disease.

HEADACHES—EYESTRAIN

Headaches are one of the most frequent and distressing maladies which usually come first for relief to the general physician. Very many headaches may properly be classified as eye symptoms, especially those chargeable to "eyestrain." These so-called "eyestrain" headaches are due to a variety of ocular causes, such as refractive errors, particularly hypermetropia, low grades of astigmatism, fatigue of the ciliary muscle, muscular imbalance, etc.

The recognition of the possibility of headache being due to eyestrain is, therefore, a matter of interest and concern to the general physician. There are a number of special features commonly associated with eyestrain headache which strongly suggest the likelihood of the eyestrain being the cause of the head distress. These special features may be briefly summarized as follows:

The *location* of the headache is not always as one might expect a helpful diagnostic aid; any area of the head may be attacked; it is, however, quite usual to have it referred to the region of the eyes—mid, supraorbital, or frontal, and quite commonly to the region of the occiput; headaches provoked by use of the eyes, notably unusual eye demands, such as "shopping," "theater," "motoring," "embroidering," are of especial significance; the time of onset, while suggestive, is not a dependable factor, even the so-called "waking headache" which appears after a good night's rest is often found to be an "eyestrain" headache, due to the fact that on awakening the accommodative function is called into instant and abrupt use and it is this accommodative strain and fatigue which plays the major rôle in headache due to eyestrain. Other suggestive factors are such "asthenopic symptoms" as blurring of vision, irritation and burning of eyes, spots before eyes,

redness of lids, blinking and lacrimation, photophobia, inability to continue sustained use of the eyes without a feeling of fatigue or strain. Very frequently sufferers from low degrees of refractive errors complain of symptoms such as vague, ill-defined headaches which completely disguise the origin of their difficulty as being due to eyestrain. A characteristic of this class of cases is that seldom do they associate their headaches and other symptoms with their eyes and few of them have impaired vision. There are other very serious eye and general diseases in which headache is commonly an outstanding symptom. One of the most destructive of eye diseases, viz., acute inflammatory glaucoma, is the cause of severe headaches and since its tendency is to rapid involvement of sight, its early recognition is paramount for conservation of vision. Fortunately, as a rule, in this disease suggestive eye symptoms, such as foggy vision, redness of the eyeball, pain in the eye itself, dilatation of the pupil, and especially increase of the intraocular tension are associated with the headache and direct one's attention to the eye as being its cause. It should be noted, however, that often in the early stages of glaucoma, the so-called "prodromal stage," these suggestive eye symptoms are often absent. These "prodromal types" should be kept strongly in mind; they are frequently only diagnosed by a very searching eye investigation. In the other variety of glaucoma—the noninflammatory type, the so-called chronic simple glaucoma—the patient may not complain of severe headache, but only, perhaps, of a vague, rather ill-defined head or eye distress and the eye exhibits no inflammatory signs, but is normal in appearance. This type of glaucoma is an insidious, destructive eye disease, common in elderly people and requires, as a rule, thorough repeated eye examinations to exclude it.

Headache usually of a severe type is also often an outstanding symptom of brain tumor. The familiar symptom triad of headache, emesis and vertigo should always arouse a suspicion of brain tumor. Examination of the eyegrounds should always be done in such cases; it frequently discloses

the characteristic eye symptoms of brain tumor, viz., optic neuritis or choked disk.

Practical Eye Diagnostic Summary.—In all patients suffering with headaches of any form, severe, vague or ill-defined, the eyes should be investigated. The presence of normal vision, the normal appearance of eyes as well as absence of complaint of direct eye symptoms, does not rule out the possibility of the eyes being accountable. In elderly patients, particularly, glaucoma is the important eye disease to exclude and since increase of tension is the outstanding symptom of glaucoma, the tension should be taken as a routine in all patients. Low grade refractive errors, astigmatism, hypermetropia, are the cause of a large number of headaches and therefore the refractive condition of the eyes should be determined. A persistent headache should always suggest brain tumor, and an eyeground examination should be made for confirmation.

EXOPHTHALMIC GOITER

(Parry's Disease; Graves' Disease; Basedow's Disease)

A great number of eye symptoms or signs have been described as associated with this disease. Among them the following may be enumerated. Exophthalmos, von Graefe's, Dalrymple's, Stellwag's, Moebius', Kocher's, Gifford's, Suker's, Jellinek-Teillais', ophthalmoplegia, etc. Of these, there are six symptoms, exophthalmos, von Graefe, Dalrymple, Stellwag, Moebius, Gifford, which are relatively constant and are commonly accepted as being a part of the symptom complex of the disease. For clinical purposes, and without regard for the various theories assigned as causal factors in their production, I have found it of advantage to group these seven symptoms or signs in the following manner: *One* of them, the *exophthalmos*, concerns the *position* of the eyeball; *four*, the *von Graefe, Dalrymple, Stellwag, and Gifford*, concern the *eyelids*; *one*, the *Moebius*, concerns the *movement* of the eyeball (convergence, etc.). These may be discussed briefly as follows:

Exophthalmos.—Exophthalmos, when apparent, is the most striking symptom of Graves' disease and is the symptom from which the term, exophthalmic goiter, usually applied to the disease originated.

In the earlier studies of the disease the "tripod" of symptoms—exophthalmos, tachycardia and thyroid enlargement—were regarded as the "diagnostic syndrome" of Graves' disease. More recent clinical research has altered and amplified this concept. The symptom of exophthalmos, however, is still regarded, with such reservations as these later researches have suggested, as an important part of the symptomatology of the disease. Formerly, it was believed that exophthalmos was an invariable accompaniment of the disease symptomatology. At present it is said to be absent in atypical cases—the so-called *formes frustes* types. Bram believes that "exophthalmos occurs sooner or later in from 65 to 85 per cent of subjects of Graves' disease."

In addition to the term, "exophthalmos," the symptom—depending somewhat upon its degree—is often described as a "bulging" or "prominence" of the eyes; also as "pop-eyes," "goggle-eyes," "proptosis," etc.

The malposition of the eyes is straight forward, the degree of prominence varying from slight protrusion, at times difficult to estimate, to extreme protrusion interfering with lid closure, the latter condition exposing the eye to the grave danger of corneal ulceration, panophthalmitis, possibly loss of the eye.

The mobility of the eye is rarely impaired to any considerable degree. These two characteristics—the straight forward proptosis and the retention of practically normal mobility of the eyeball, are of considerable value in differentiating from an exophthalmos due to orbital or nasal accessory sinus pathology.

Both eyes are usually involved. A difference in degree between the two eyes is frequent, notably in the early stages of the disease; only one eye may also be affected, the other appearing normal.

Willebrand and Saenger report that in one-seventh of the cases the exophthalmos is unilateral or is larger on one side. It is generally regarded as the first *eye* symptom to appear, though in the majority of cases it is a late manifestation occurring subsequent to the other general manifestations, and persisting—possibly the last symptom to disappear. Its onset is more or less insidious and its evolution as a rule gradual. In certain cases, however, in which such factors as violent freight, emotional excitement, etc., are profound, its onset may be abrupt. Falta, for example, states that exophthalmos may even come on in one night or in a few days; Dock, that “it may come in in a few days or even minutes, but usually does so slowly, sometimes irregularly.” Apparently there is no dependable ratio between the degree of the exophthalmos, its distribution—mono- or binocular—in relation to the thyroid enlargement and the intensity of the general symptomatology.

The various views assigned as etiologic factors in the production of the exophthalmos are summarized by Fuchs as follows: (a) Engorgement of the orbital vessels; (b) irritation of the sympathetic causing tonic contraction of the unstriated muscle fibers running in the orbit from the equator of the eye to the orbital septum (Landstrom); (c) to the accumulation of fat in the orbit with edema of the ocular muscles (Foster Moore); (d) to suprarenal insufficiency (Shapiro and Marine). Plummer and Wider in an extended review of the subject state: “The vast amount of clinical evidence still indicates that the immediate cause of exophthalmos in exophthalmic goiter is closely linked with actual changes in the function and pathology of the thyroid gland.”

It is to be noted that exophthalmos often occurs independent of endocrine difficulties, notably in corpulent individuals, patients with high myopia and those afflicted with anatomical peculiarities such as “tower skull” (Thurmschädel), lack of tone of the recti muscles, orbital and nasal accessory sinus disease, and aneurysm. It has also been reported as occurring in chronic nephritis.

Various instruments are in use to measure the degree of exophthalmos—the exophthalmometer, statometer. Probably as satisfactory a means is to apply a straight edge vertically to the upper and lower orbital margins, the lids being closed. This edge, thus applied, in the normal position of the globe should just press gently upon the apex of the cornea through the closed lids.

von Graefe's Sign.—Normally the upper lid covers the same ratio of the cornea in the upward and downward movements of the globe and no portion of the sclerotic coat is visible. In the von Graefe sign as the eye is directed downward the upper lid does not follow it perfectly but lags behind with the result that a varying amount of sclera is exposed. The sign is elicited in the following manner: An object is held in front of and slightly below the patient's eye and he is directed to follow its movements without movement of his head. The object is then *slowly* moved downward and if the von Graefe's sign be present a varying rim of sclera will be seen between the upper margin of the cornea and the lower margin of the upper lid. Occasionally also, as the eye is moved in the upward direction the upper lid proceeds more rapidly than the eyeball, an impairment of synchronous function will become evident, possibly in the form of a "jerking" of the upper lid.

Solomon Solis-Cohen (referred to by Bram) describes what he terms the "hitch sign" of the upper lid which he considers the larval form of von Graefe's sign as follows: "When the eyelid begins its downward course over the eyeball it stops short (the 'hitch'), then proceeds downward to complete its descent. When the lid is again raised it does so with a continuous movement, but presents a sudden hesitancy or 'hitch' in its upward course." von Graefe's sign while an important eye sign of Graves' disease may be entirely absent, be unilateral though usually involving both eyes, may fluctuate, and apparently exhibit no dependable association with the goiter itself or the exophthalmos. It is said, however, to appear as an earlier eye manifestation and persists longer than the exoph-

thalmos. Reports as to the incidence of the symptom vary from 15 to 55 per cent.

Sharkey (referred to by Foster Moore) states that the symptom is not limited to Graves' disease but that of 613 cases of all kinds of disease, excluding Graves', it was present in 12 cases and that many people can produce it voluntarily.

Willebrand and Saenger (referred to by Dock) give five theories of the cause of the symptom, viz.: Sympathetic; central; action of the orbital vessels upon the levator; insufficiency of the orbicularis; increase of the forces which cause elevation.

Dalrymple's Sign.—This sign consists of a retraction of the upper lid with consequent widening of the palpebral fissure, the sclera being exposed above and below the cornea. This produces in the patient the so-called "*look of fright*" or "*staring expression*." According to Dock, "it occurs early, is rarely absent, varies from day to day and sometimes is more distinct on one side." This sign is also found in hysteria, tetanus, pregnancy, and in maniacal maladies. Its cause is attributed to spastic contraction of the musculus tarsalis superior due to irritation of the sympathetic (Fuchs).

Stellwag's Sign.—This sign consists of a diminished frequency of winking. Normally the function of winking distributes the lacrimal fluid over the cornea, bathes it, clears the cornea of dust and prevents the corneal layers from drying. Winking takes place normally, approximately three to ten times per minute; in Graves' disease it may not take place more than once in several minutes. Interference with this corneal protective function exposes it to irritation and infection. It is not uncommonly an early symptom and is said to occur in 30 to 50 per cent of cases.

Moebius' Sign.—This sign is a reduction in the convergence function not attributable to muscular paralysis or exophthalmos.

Gifford's Sign.—In this sign difficulty is experienced in everting the eyelid, and is regarded as of frequent occurrence.

The foregoing résumé of the ocular manifestations of

Graves' disease emphasizes the value of these symptoms to the clinician as aids in the diagnosis and in estimating the clinical progress of the disease.

Practical Eye Diagnostic Summary.—In all cases of suspected exophthalmic goiter, the eye and its appendages should be examined. The eye symptoms exhibited concern mainly the position of the eyeball, lid movement and convergence. The various impairments of these—referred to—should be investigated in a detailed way in every case.

ARTERIOSCLEROSIS

In November, 1931 a patient, aged fifty-nine, consulted me for change in reading glasses; no general complaints; considered himself to be in excellent physical condition. Examination of the eyegrounds disclosed an arteriosclerosis of the retinal vessels of marked degree. He was advised to have a general physical examination. Within the following four months the patient was given a thorough general physical examination in two different outstandingly recognized clinics. The findings of both clinics, other than hypertension of moderate degree, were negative. Approximately five months later the patient while attending a hockey game was stricken with cerebral hemorrhage from which he later died.

According to Fraser's survey of life insurance mortality experience for the year 1934, "the mortality from the cardiovascular-renal group (a group that includes heart disease, chronic kidney disease, apoplexy, and arteriosclerosis) far outweigh those from any other cause."

The sequential relationship of hypertension, arteriosclerosis, the cardiovascular-renal group of diseases, and vascular cerebral pathology, is, as yet, undetermined. Whatever the final verdict may be, it is exceedingly probable that arteriosclerosis will occupy a prominent place in the final estimate. As Osler well says, "the tragedies of life are largely arterial," and one may add, arteriosclerosis plays a major rôle in their enactment. Early recognition of a beginning arteriosclerosis is therefore of outstanding value in conserving life. The retinal vessels, in common with other general vascular structures share in the attack of sclerotic processes; often they present evidences of such invasion before it is manifested in other portions of the body. It is not too much to say that no part of the body offers a more fruitful field and relatively easy

method of obtaining reliable data concerning the condition of vascular structures than that offered by the retinal vessels and fundus. Numerous observers confirm this view.

Osler, for example, states, "Of all the vessels in which to see early thickening, the retinal arteries are the most impor-

Fig. 150.—A case of arteriosclerotic retinitis. From a woman aged sixty-five, whose systolic blood pressure was greater than 300 mm. She died of "a stroke totally blind" four years and four months after the drawing was made. The arteries are very bright, the lower one showing a dotted reflex, and when seen three years and one month later many of them were converted into fibrous threads. The veins are deeply cut into by the arteries; in one place a vein rides over a thickened artery. A few hemorrhages and a number of the discrete dots of arteriosclerotic retinitis are seen. The disk edges are blurred. (Moore, "Medical Ophthalmology," J. and A. Churchill, Publisher)

tant." Gunn observes, "ophthalmoscopic examination is one of the most ready clinical means for the early detection of important arterial changes," and Friedenwald notes, "the

most important aspect of ocular and especially retinal arteriosclerosis is its diagnostic value in relation to general vascular disease." Cabot writes, "arteriosclerosis may appear earlier or more clearly in the retina than elsewhere."

The pathologic histology of retinal arteriosclerosis is of interest in interpreting the varied symptomatology. Adams' view is, "microscopically, the process is seen to be due to a chronic inflammatory process, there being a proliferation of the endothelium of the tunica intima, and at the same time new formation of connective tissue and especially of elastic tissue. The endothelial proliferation occurs both in the arteries and veins." The obstruction of the retinal vessels, which those various lesions produce, affects the nutrition of the retinal structures and is therefore a major factor in impaired retinal function.

The arteriosclerotic changes which affect the retina and retinal vessels are many and various. The following abridged outline of deSchweinitz' comprehensive summary presents the usual changes encountered. (Fig. 150.)

"Alterations in the retinal vessels are also caused by chronic nephritis and general arteriosclerosis and present the following ophthalmoscopic appearances: (1) Alterations in the course and caliber of the retinal arteries, such as undue tortuosity, which is not significant unless it is associated with other evidence of disease; in the size and breadth of the retinal arteries, presenting as it were a beaded appearance. (2) Alterations in the reflections from and the translucency of the walls of the retinal arteries, manifesting themselves (*a*) in increased distinctness of the central light streak on the retinal vessel and an unusually light color of the entire breadth of the artery; (*b*) loss of translucency, so that it is impossible to see, as is possible in the normal state, through the artery and underlying vein at the point of crossing; (*c*) positive changes in the arterial walls consisting of whitish stripes, indicating degeneration of the walls or infiltration of the perivascular lymph-sheaths (perivasculitis). (3) Alteration in the course and caliber of the veins, together with signs of

mechanical pressure, manifesting themselves (a) in undue tortuosity, which as in the case of the arteries is not significant except in the presence of other disease; (b) alternate contractions and dilatations; (c) an impeded venous circulation where a diseased artery crosses it. The last is a sign of the utmost importance. (d) Changes in the venous walls, precisely as they occur in the arteries, so that whitish stripes border the vessel and are indications of degeneration in its walls. Often associated with this one may see varicosities. (4) Edema of the retina, manifesting itself (a) as a grayish opacity, which may be present in the immediate neighborhood of the papilla, or in spots over the eyeground and along the course of the vessels, looking like a fine gray haze or in little fluffy islands far out in the periphery. (5) Hemorrhages, manifesting themselves as linear extravasations along the course of the vessels, roundish infiltrations scattered over the fundus, or in droplike form."

He further adds, "the *significance* of these lesions is of serious import. In addition to their relation to nephritis, they may be the forerunners of vascular sclerosis of the brain or indicate the presence of disease of the cerebral arteries. Their subjects are liable to hemorrhage in the brain and all its consequences." The consensus of opinion is that no one sign or symptom in the retinal vessels or retina is pathognomonic of retinal arteriosclerosis. Moore, for example, points out that tortuosity of the arteries of itself is not a reliable index; deSchweinitz emphasizes, however, that a well marked tortuosity affecting the smaller vessels of the macula, indicates a marked degree of arteriosclerosis.

Optic atrophy of gradual development may supervene as a result of the reduced blood supply occasioned by the sclerotic vascular disease. Oatman calls attention to a pulsation in the arteries, so-called "locomotion pulse" as one of the early evidences of retinal arteriosclerosis. He emphasizes as a diagnostic aid the pulsation pressure test, viz.: "Healthy retinal vessels are very compressible while sclerosed vessels are comparatively incompressible. If gradually increased pressure is

applied by the finger to the eye the ophthalmoscope will disclose (1) strong venous pulsation on the disk; (2) arterial pulsation; (3) cessation of circulation and blanching of the vessels. Rigid vessels resist pressure and where retinal arteriosclerosis is advanced neither venous pulsation nor blanching of the vessels can be produced by pressing on the globe with the finger."

Other suggestive symptoms of arteriosclerosis are spontaneous subconjunctival hemorrhages in adults, edema of the lids and recurring conjunctival chemosis. Moore and many other observers stress the diagnostic value of the peculiar phenomena occurring at the arteriovenous crossings, such as indentations and obscuration of the underlying vessel, diver-

Fig. 151.—To show the riding of a vein over a thickened artery in the retina. The shaded band on each side of the artery indicates its visible coats. From a man of sixty-five whose systolic blood pressure was 265 mm. The appearances were quite unchanged at the end of two years. (Moore, "Medical Ophthalmology," J. and A. Churchill, Publisher.)

sion of its course and interference with its visibility for short distances on either side of the crossing; these changes he regards as evidence of a high degree of sclerosis (Fig. 151). Knapp emphasizes that in appraising the ophthalmoscopic findings, refractive errors, conditions of acute toxemia occurring in acute Bright's disease, severe influenza, and a failing heart must be excluded. Thorington mentions the presence of sclerosis in retinitis pigmentosa. Cerebral arteriosclerosis is not necessarily to be predicated on a retinal arteriosclerosis as the two may not coexist. Herter, however, states that a positive finding of sclerosis of the retinal vessels assumes a similar condition in the cerebral vessels, but not the reverse.

Moore believes that where disease of the retinal arteries is evident, cerebral vascular disease is also present, but that in 30 per cent of cases even an advanced disease of the cerebral vessels may be present without the retinal vessels being demonstrably involved. As to prognosis, Moore states the tenure of life of patients who are the subjects of retinal arteriosclerosis is uncertain, but a considerable number live for several or many years. Adams concludes that the prognosis is dependent upon the associated renal and cardiac changes and that it is aggravated by the presence of albuminuria and that it is better in older people.

Practical Eyo Diagnostic Summary.—Early manifestations of general arteriosclerosis are frequently seen in retinal vessels. Their early recognition have an important bearing in relation to the cardiovascular-renal group of diseases. The presence of sclerotic changes in the retinal vessels suggests arteriosclerosis, syphilis, or nephritis. Routine examination of the eyegrounds is therefore of outstanding value in general examination.

The important changes to be sought for in ophthalmoscopic examination of the retinal vessels are—undue tortuosity, particularly of the vessels near the macula, beaded appearance—accentuation of the central light stream and sheathings (whitish stripes bordering the vessels) of the sheaths, indentation of and lack of transparency at vessel crossings, locomotion pulse, changes in caliber, retinal infiltrations; in addition, edema (grayish opacity) of the retina, retinal hemorrhages, the pulsation pressure test phenomena, edema of the lids, recurring conjunctival chemosis, and subconjunctival hemorrhages.

BRAIN ABSCESS

In December, 1930 a young man of twenty-four came under my care suffering from severe, persistent headaches. Several years previously he had had a right simple mastoid operation. Eye examination was negative. Other findings, however, suggested a suspicion of brain abscess, which was concurred in by an eminent neurologist. Blood examination, however, disclosed the Plasmodium malariae of Laverin and the diagnosis of malaria.

This case is cited more particularly to stress the value of "routine" in examination.

The diagnosis of brain abscess is almost always difficult. It is generally accepted that they have their origin as complications of infective processes originating outside the cranial cavity, such as diseases of the ear, mastoid, nasal accessory sinuses, heart, lungs, etc. In making the diagnosis of brain abscess, therefore, it is necessary to establish the causal rela-

tion between the original focus and in addition exclude as possible explanations of the symptoms presented a host of other diseases such as brain tumor, meningitis, apoplexy, cerebral syphilis, encephalitis lethargica, etc. A problem of this magnitude demands that every source of possible aid be utilized. The eye not infrequently exhibits symptoms in brain abscess which may, in connection with the other symptoms, prove of considerable value in the diagnosis and localization. An enumeration of the eye symptoms which may occur in the various types of brain abscess includes the following: Photophobia, diplopia, optic neuritis, papillitis, choked disk, nystagmus, pupillary disturbance, hemianopsia, oculomotor and abducent nerve paralysis and sensory aphasia. The most important of these is optic neuritis. According to Gowers, optic neuritis occurs in two thirds of the cases and if the abscess has existed for more than four weeks it is found in three fourths of the cases; also, that if it is limited to, or more pronounced on one side the abscess is likely to be on that side. Practically all observers agree that the optic neuritis, in particular the swelling of the papilla, is seldom as marked as in brain tumor, and also that optic neuritis and choked disk are more frequent manifestations of brain tumor and meningitis than of brain abscess. It is also said that optic neuritis and choked disk are more common with cerebellar than with cerebral abscess. Choked disk is generally regarded as an expression of extreme increased intracranial pressure, as may occur in brain tumor. It is not a usual manifestation of brain abscess but is more common in brain tumor, occurring in 71 per cent of cases; in brain abscess in 2.2 per cent (Uhthoff), due perhaps to the usual absence of increased intracranial pressure in brain abscess and its usual presence in brain tumor. Sharpe, for example, states, "Unlike most brain tumors (excluding the gliomas) which produce an increase of the intracranial pressure by their added tissue formation or by a blockage of the ventricles, brain abscesses, on the contrary, replace brain tissue so that unless the escape of cerebrospinal fluid from ventricles is blocked by a large subtentorial abscess for-

mation there are produced no signs of a marked increase of the intracranial pressure."

Iggleton's deductions are, "A moderate grade of papilledema is a frequent manifestation of cerebellar abscess; papilledema is frequently seen in occipital lobe abscess; papilledema is usually absent in front lobe abscess; transient or fixed hemianopsia of the homonymous type, for form and colors is a valuable localizing sign of temporosphenoidal lobe abscess and should always be sought for; vertical nystagmus and lateral deviation of the eyes when present are definite indications of cerebellar involvement; ocular paralysis is of no localizing value."

Photophobia may be present in the early stages, but it is of no determining value as to localization or stage of abscess. Diplopia occurs occasionally in temporosphenoidal and frontal lobe abscess. Wyllie states that the state of the pupil does not assist in the diagnosing of the abscess but is of decided value in deciding the stage and the side on which the abscess is located—equal pupils which respond actively to light and accommodation indicate the early purulent stage; if the pupils lose their activity and become sluggish or stable it is an indication of the terminal stage; if unequal, one being widely dilated, the abscess will likely be found on the side of the widely dilated one; if both pupils are widely dilated the abscess is probably large. Vision may be affected and its prognosis is uncertain depending on all the factors entering into the case. While the eye symptoms of brain abscess are of aid in diagnosis their absence is not to be interpreted as an indication that a brain abscess is not present.

Practical Eye Diagnostic Summary.—In all suspected cases of brain abscess, a field of vision for both form and color should be taken with especial emphasis on disclosing if an homonymous hemianopsia be present which is a valuable eye symptom, pointing to a temporosphenoidal lobe abscess. The findings on first examination may not be complete but suggestive, later, tests may confirm the early suggestive features, hence, all the foregoing eye tests should be repeated at frequent intervals. The pupils should be carefully examined for equality and reaction. The eyegrounds, especially the papilla, carefully studied for early evidences of optic neuritis.

BRAIN TUMOR

In June, 1930 a young girl of nineteen was referred to me for an eye examination to determine if glasses might not relieve the severe headaches from which she had suffered for some time. She had recently been operated for gallbladder infection, the diagnosis of this condition being largely based on the presence of gastro-intestinal disturbance, persistent severe headaches and jaundice. No relief resulted from the operation. Eye strain was considered as a possible cause of the headaches. The eye examination disclosed a well-marked choked disk involving both eyes and the diagnosis of brain tumor was made.

The eye symptoms of brain tumor are of outstanding significance, diagnostically and prognostically, and frequently are determining factors in appraising the clinical progress of the cerebral lesion and its proper therapeutic management. It should be recalled, however, that these eye symptoms are not of themselves as a rule determining elements but must be considered only as a part of the clinical ensemble of symptoms presented. The chief eye symptoms of brain tumor are: (1) Those involving the optic papilla and retina; (2) changes in the visual fields for form and color and alterations of the blind spot; (3) impairment of the light sense. Of these symptoms the most important is that affecting the optic nerve head, commonly referred to as choked disk, papilledema, papillitis, optic neuritis or by the German designation, "Stauungspapille." It is present in 80 to 90 per cent of cases. Foster states that choked disk is absent in only 5 to 10 per cent of cases and these are mainly tumors of the frontal brain and of the hypophysis. As a preliminary to the discussion of the symptom, choked disk, it is well to refer briefly to certain anatomical relations of the cranial cavity, brain, optic nerve and retina which have an important bearing on the evolution of this eye symptom and the general accepted theory of its production. (Fig. 152.)

The eyeball, optic nerve and retina are essentially outgrowths of the brain. The retina is in reality an expansion of the brain and the optic nerve may be regarded as a cerebral tract. Each optic nerve trunk is made up of nerve fibers separated by neuroglia and held together by connective tissue.

Fig. 152.—Longitudinal section through the head of the optic nerve. In its passage through the scleroticocoroidal canal the optic nerve shows an irregular conical contraction. The fibers of the nerve are collected into bundles, *n*, separated by septa, *s*. Under the form of rows of nuclei, which belong to the neuroglia cells, the continuation of the septa can be followed to the head of the optic nerve. The axis of the nerve is occupied by the central vein, *v*, and the central artery, *a*, which is situated to the nasal side of the vein. The optic nerve is traversed transversely by the lamina cribrosa, which separates the trunk from the head of the nerve. The fibers of the lamina cribrosa arise from the wall of the scleral canal, traverse the nerve in a slightly concave arch (the concavity being directed to the front), and are inserted into the connective tissue that accompanies the central vessels. About at the level of the inner layers of the choroid, the nerve fibers diverge like a sheaf, so as to form a funnel-shaped depression—the vascular funnel, *G*. More fibers pass to the nasal than to the temporal side of the papilla, for which reason the former side is the higher. The fibers of the optic nerve pass over into the fiber layer (1) of the retina. Succeeding this are the other layers of the retina, namely the layer of ganglion cells (2), the inner plexiform layer (3), the layer of inner granules or bipolar cells (4), the outer plexiform layer (5), the layer of the outer granules or of the bodies of the visual cells (6), the limitans externa (7), and the layer of rods and cones (8). The layers of the retina stop short at the head of the optic nerve, the outermost layer, 8, extending the furthest in. The innermost fibers of the sclera which form the wall of the scleral canal, accompany the optic nerve backward and form its pial sheath, *P*, which is in intimate relation with it. At a point further back from the nerve head the outer layers of the sclera are reflected backward and form the dural sheath, *D*, which envelops the nerve loosely. Between these two sheaths lies a third, the arachnoid sheath, *A*, which divides the intervaginal space of the optic nerve into the subdural space, *sd*, and the subarachnoid space,

Lymph channels occur between the connective tissue and the bundles. The nerve trunk is surrounded by three enveloping sheaths; the dura, arachnoid and pia, which are the direct continuation of the cerebral meninges. Between the dura and pia is the intravaginal space which is divided by the arachnoid sheath into the lymph spaces, the subdural and subarachnoid. Both of these lymph spaces originate in and are continuous with the corresponding cerebral channels. These enveloping sheaths terminate by a cul-de-sac in the sclerotic coat of the eye near the lamina cribrosa. The central vessels (artery and vein) of the retina run in the axis of the optic nerve to the optic papilla where they enter the eyeball and spread out over the nerve head as the central retinal vessels. They are presumed to have no anastomosis and are regarded as end-arteries. The connection of the cerebral lymph spaces with the sheaths enveloping the optic nerve, and in particular their termination in a cul-de-sac in the immediate neighborhood of the optic nerve, favors blockade and compression of the nerve at this point. This anatomical arrangement explains the readiness with which an increase of intracranial pressure may by compression affect the nerve head and retinal vessels and produce in the eyegrounds the familiar ophthalmoscopic picture of

sa. Anteriorly, both end by a cul-de-sac in the substance of the sclera; *b*, is the cross section of one of the numerous subarachnoid trabeculae which connect the arachnoid to the pial sheath. In the wall of the scleral canal is seen the cross section of some blood vessels, belonging to Zinn's scleral circle. Between the sclera, *S*, and the retina, *R*, lies the choroid, *Ch*. The innermost layer of the latter, the lamina vitrea, 10, is the one that extends the furthest in toward the nerve head, and the fibers of the nerve are constricted by the edge of the lamina. Upon the lamina vitrea lies the pigment epithelium, 9, which belongs to the retina and which on the nasal side extends as far as the lamina vitrea, but on the temporal side stops somewhat short of it. On both sides the pigment epithelium gets to be thicker and more pigmented toward its edge—a state of things which answers to the choroidal ring that can be seen with the ophthalmoscope. The succeeding layers of the choroid, the choriocapillaris, 11, and the layer of medium and large-sized vessels, 12, do not extend quite up to the optic nerve on the temporal side, because a layer of connective tissue representing a continuation of the sclera juts in between the two. (Fuchs-Duane, "Textbook of Ophthalmology," Courtesy of J. B. Lippincott Co.)

choked disk. The fibers making up the optic nerve along with the vessels imbedded in their substance enter the back part of the eyeball through a rather intricate aperture known as the foramen sclerae and on reaching the interior eye spread out over its posterior inner surface to form a nerve carpet, the retina. The optic nerve trunk does not enter the eyeball at the foramen sclerae through a single large opening but in the following manner (modified from Fuchs). The sclera divides into an outer and inner portion. The outer portion, constituting two thirds of its thickness, is not perforated at all, but is reflected backward and enfolds the trunk of the nerve forming the dural sheath; the inner portion, along with a small portion of choroid process traverses inward forming a septum or diaphragm which is perforated by numerous openings through which the separate bundles of nerve fibers pass. This perforated diaphragm resembles a sieve, hence the name "lamina cribrosa" applied to it. The optic nerve at the foramen sclerae and especially at the lamina cribrosa is tightly enclosed between firm fibrous walls and when swelling of the optic nerve takes place, constriction and strangulation of it usually occurs. Viewed with the ophthalmoscope, the lamina cribrosa, when present, appears on the disk surface as a small stippled zone made up of grayish dots and white interspaces. The dots are the nerve fibers and the white interspaces are the septal partitions between the apertures. The central vessels enter with the nerve fibers, divide and traverse the retinal surface. The separation or diverging of the nerve fibers and vessels on the nerve head produces a funnel-like depression called the vascular or physiologic cup the bottom of which may present a stippled appearance, the lamina cribrosa. The area of entrance of the nerve fibers and vessels to the eyeball is known variously as the nerve head, the optic disk or papilla. The two optic nerve trunks proceed backward from the eyeball and join at the chiasm. In the chiasm the fibers of each trunk divide, semidecussate and form optic tracts, each of which is a composite of nerve fibers from its own and the opposite side, a left and right. The optic tracts

proceed backward respectively to the right and left primary subcortical optic centers and visual areas in the occipital lobe. (Fig. 153.) The nerve fibers of accommodation, convergence and of the pupil pass from the optic tract to the oculomotor nucleus and from this nucleus send fibers in the trunk of the oculomotor nerve to the pupil, to the muscles of accommodation and convergence. This semidecussation of nerve fibers at the chiasm and the distribution of the tracts explains the various pupillary, accommodation, convergence and hemianopic phenomena frequently exhibited in cerebral neoplasms and other intracranial disturbances which often provide important eye symptomatology in the diagnosis and localization of the lesion. The chiasm rests upon the sphenoid bone and is in intimate relation with the pituitary body, the anterior end of the third ventricle, the infundibulum, internal carotids and the meninges.

Many theories have been advanced to explain the development of choked disk, notably the mechanical and the toxic or inflammatory (Fig. 154). The consensus of opinion favors the mechanical theory. Cushing observes, "It seems in all probability a stasis edema from the forcing of the cerebrospinal fluid into the meningeal sheath which invests the optic nerve." Fuchs' comprehensive explanation of the way choked disk may be produced by an intracranial growth is of interest, "A brain tumor as a result of its growth arrogates constantly more and more space to itself within the cranial cavity. Hence, as the skull is unyielding there arises an increase in the intracranial pressure. Owing to this increase the return flow of lymph in and about the optic nerve is impeded and a stasis of lymph occurs producing an edema of the nerve trunk. This edema causes a compression of the central vessels, a compression which makes its influence felt, sooner and to a higher degree, in the central vein of the optic nerve than in the central artery. As there is constantly pouring into the papilla through the artery a quantity of blood which cannot be completely carried away again by the contracted central vein, venous engorgement of the optic nerve and consequently

swelling of the latter developed. This swelling of the nerve leads to its incarceration at the spot where it fits so tightly

Fig. 154.—Longitudinal section through the head of the optic nerve in choked disk (magnified 14×2). The disk is greatly swollen, so as to project above the level of the adjacent retina and form at the base an annular protrusion, *n*. There is a cellular infiltration, particularly along the minuter blood vessels, *e*, for which reason the latter appear specially prominent. The retina, *r*, is thrown into folds about the circumference of the disk, in consequence of the swelling of the latter; the choroid, *ch*, and the sclera, *s*, are normal, as is the optic nerve posterior to the lamina cribrosa. Here there is present, simply a dilatation of the intervaginal space, *i*, through accumulation of fluid, by virtue of which the greatly folded arachnoid sheath, *ar*, becomes especially prominent; *du*, dural sheath; *p*, pial sheath. (Fuchs-Duane, "Text-book of Ophthalmology," J. B. Lippincott Co.)

in the foramen sclerae and consequently extreme edema develops in the strangulated nerve head. This edema constitutes what is known as choked disk which therefore consti-

radiation, *S*; the pupillary fibers, *m*, go to both oculomotor nuclei, *K* and *K*₁. Each of these latter consists of a series of partial nuclei, one of which sends fibers, *P*, to the sphincter iridis, another sends fibers, *A*, to the ciliary muscle (muscle of accommodation), and a third sends fibers, *C*, to the converging muscle (internal rectus), *i*. All three fibers run in the trunk of the oculomotor nerve, *Oc*. Division of the optic tract at *gg* or *ee* produces right hemianopsia, and in the former case there would theoretically be no reaction to light on illuminating the left half of either retina (hemikinesis). Division of the chiasm at *ss* produces temporal hemianopsia. Division of the fibers, *m*, abolishes the reaction of the pupil to light, but leaves the associated reaction of the pupil to accommodation and convergence unaffected. (Fuchs-Duane, "Textbook of Ophthalmology," Courtesy of J. B. Lippincott Co.)

tutes a very important symptom of increase of the cerebral pressure." The ophthalmoscopic picture of choked disk has been summarized by Marcus Gunn in five stages:

Fig. 154a.—Choked disk at its acme. Scarcely a trace can be seen of the margins of the papilla, but the latter seem to send tonguelike processes into the retina. The papilla is distinctly elevated, as can be seen from the course of the vessels, and exhibits a radiating striation. A number of hemorrhages, also striate in form, give the disk quite a specific appearance. The disproportion between the arteries and the veins is so great at the acme that the former are scarcely visible, while the latter leave the papilla as broad, tortuous bands. Some white patches of degeneration are visible in the retina. There are only a few retinal hemorrhages in this case, but they are often much more numerous. The vision in this patient was normal. (Adam Foster, "Ophthalmoscopic Diagnosis.")

1. The earliest ophthalmoscopic signs are increased redness of the disk, loss of definition in its edges, slight prominence of its surface and narrowing of the physiologic pit.

2. As a rate which varies much in different cases and which seems to bear a decided relation to the degree of intracranial tension, the swelling of the papilla increases, the physiological pit disappears and the disk edges become quite obscured. Along with these signs there is now slight haziness of the surrounding retina and the retinal veins show evidence of retarded circulation.

3. In an advancing case the next alteration consists in further swelling of the papilla so that it becomes more prominent and occupies a larger fundus area, the venous distention becoming more marked. Fine folds not infrequently appear in the edematous retina, particularly between the disk and macula and there may be retinal hemorrhages.

4. The papilla becomes more opaque and sometimes more prominent, the hemorrhages increase in size and number and there are inflammatory exudations on the disk and surrounding retina. At this stage vision has become impaired.

5. The next stage consists in a gradually decreasing vascularity of the papilla, part of its surface becoming paler than normal, while the prominence either persists or slowly subsides. At this time also we first note a change in the branches of the central artery in the form of diminished breadth—the state of atrophy with inevitable blindness.

From the foregoing summary it is evident that in making an ophthalmoscopic inspection of the eyegrounds for suspected choked disk our study of the nerve head should concentrate on the following five cardinal features: (1) Its color and transparency; (2) definition of its margins or disk outline; (3) condition of level; (4) appearance of the physiologic pit; (5) condition of vessels; ratio in size of the retinal arteries and veins; evidences of retinal edema and retinal hemorrhages. The various stage above outlined in an advancing process show step by step progressive involvement of these five cardinal features. The striking eyeground change of brain tumor is that of the nerve head, choked disk. It is markedly swollen and projects into the vitreous. Its edges overhang and the whole appearance resembles a gray mushroom. The vessels

emerging from the vascular funnel ascend over this mushroom swelling and may disappear as they descend its sides. The disk outlines, while more or less disturbed are still defined.

The second striking change is in the retinal vessels, the veins are increased in size and the arteries contracted. The height of the swelling is estimated with the ophthalmoscope by comparing the refraction of the surrounding retina with the summit of the disk elevation, 3 diopters corresponding to 1 mm. of elevation. A generally accepted rule is that the disk swelling must show an elevation of at least 2 diopters in order to be classified as a choked disk. Sharpe deplors the usual custom of relying wholly upon a disk elevation of 2 diopters as an indication of intracranial pressure signifying a brain tumor. He emphasizes that when this amount of swelling occurs in the disk it is a late manifestation of intracranial pressure and of brain tumor and that the patient's chance of operative relief, conservation of vision, etc., correspondingly suffer when reliance is placed on such a late development. He points out that the earlier evidences of disk and retinal vessel involvement which indicate intracranial pressure should be looked for and accepted as definite evidences of increased pressure intracranially. These early signs are slight dilatation of the retinal veins and a blurring of the nasal margin of the disk, no "measurable swelling" of the disk being exhibited. These early disk and vessel changes must be examined frequently to note their progress and they should, he advises, be corroborated as evidences of increased intracranial pressure by lumbar puncture and the spinal mercurial manometer.

Visual impairment is exceedingly variable. It is often normal even in a well marked choked disk. It is not affected early in brain tumor due to the fact that the choked disk in such cases antedates the visual impairment and choked disk is, as a rule, a relatively late manifestation of brain tumor. Impairment of vision, therefore, is not a dependable symptom as a sign that choked disk is not present. It is necessary in every case of suspected brain tumor, even when the vision

is normal, to examine the eyegrounds to determine if a choked disk be present. In brain tumor the disk involvement is almost always sooner or later bilateral. Horsley believes that it is apt to appear earlier on the side of the lesion. Neither the size of the tumor, the age of the process, its situation, its unilateral exhibition or intensity are of dependable diagnostic or localizing value. Small tumors frequently cause choked disk while large ones fail to produce the symptom. Tumors of the posterior fossa (cerebellum) are the ones with which it is most frequently encountered and it is usually an earlier symptom in tumors of this locality than in tumors of the cerebrum. Cerebellar tumors and those in the midbrain and the thalamus are reputed to produce a more intense choked disk with rapid invasion of visual function than those of the cerebrum, the subcortical, parietal or frontal regions. Tumors of the parieto-occipital regions, of the corpora quadrigemina and of the cerebellum are said to produce the highest percentage of choked disk and that pontine tumors and those of subcortical origin comprise the majority of cases in which the symptom is absent. The types of brain tumor usually encountered are glioma and sarcoma, in children the solitary tubercle. Choked disk is not exclusively a symptom of brain tumor; it may be present in albuminuric retinitis, brain injuries, concussion, apoplexy, thrombosis, the internal type of hydrocephalus, meningitis, etc. The visual field changes which may be exhibited are concentric contractions, possibly inversion of the color fields and enlargement of the blind spot. The pupillary symptoms manifested are occasionally of helpful diagnostic value. Radiations of white lines or dots about the macula resembling the "stellate figure" associated with albuminuric retinitis, sometimes occur (in 15 per cent, Patton).

Practical Eye Diagnostic Summary.—There are no external changes of the eyeball which suggest a brain tumor. Vision may be normal in a patient with brain tumor even when there is a well marked choked disk present. Choked disk is a dependable symptom of brain tumor, occurring in 80 to 90 per cent of cases. The only safe course in all suspected cases, particularly those which exhibit the familiar symptom triad of headache, vomiting and vertigo,

commonly associated with brain tumor, is to examine the eyegrounds with the ophthalmoscope. Such examinations should be repeated at frequent intervals. Choked disk is a relatively late manifestation of brain tumor. Early eyeground evidences of increased intracranial pressure are slight dilatation of the retinal veins and blurring of the nasal margin of the disk without a measurable swelling of the disk. These should be looked for and confirmed by lumbar puncture and the spinal manometer. The specific ophthalmoscopic evidences of choked disk are a grayish swelling of the disk surface of a mushroom character reaching a height of not less than 2 diopters, the definition of its margins being more or less maintained, the vessels being interrupted or disappearing as they descend along the sides of the disk swelling; the retinal veins being dilated, the arteries contracted. Such changes are, as a rule, bilateral but may be unilateral or more accentuated on one side. Any change, however, of the disk, such as increased redness, blurring of its edges, slight prominence of its surfaces, etc., should cause concern and the possibility of a brain tumor may be considered until it has been definitely excluded. A visual field test for form and color and of the blind spot should be included in the examination.

EPIDEMIC ENCEPHALITIS

(Encephalitis Lethargica; Sleeping Sickness; Nona)

This disease has an added interest in view of the recent epidemics in Paris, Illinois, in 1932, and in St. Louis city and county in 1933.

All medical writers are in agreement that eye symptoms are almost always a conspicuous feature of this disease, particularly in its early stages, and that their presence in connection with other symptoms is of distinct value in establishing the diagnosis.

Barker, for example, points out that "In the acute or florid stage or first main stage, we meet most often with either, (1) a somnolent-*ophthalmoplegic* syndrome or, (2) an irritative hyperkinetic syndrome (either choreatic or myoclonic)," and he adds that "a triad of symptoms—fever, somnolence and *ophthalmoplegia*—characterize the lethargic type of encephalitis."

Among the eye symptoms which have been observed in this disease are the following: Ptosis, diplopia, accommodative pareses or paralyses, *ophthalmoplegia* of all varieties, complete partial ex- or intrinsic, impairment of globe movement upward or downward, nystagmus, "oculogyric crisis," blepharospasm, inequalities and irregularities of the pupil, im-

paired pupillary reflexes, mydriasis, myosis, Argyll Robertson pupil, optic neuritis, papilledema, oscillation of the globe, photophobia, "myostatic rigidity" of the eyes, etc.

An analysis of these ocular manifestations discloses that practically all of those enumerated have as their underlying pathology a paresis or paralysis of the nerves which supply eye structures and upon which these structures depend for functional integrity.

The pareses or paralyzes of the various ocular structures are more or less erratic and capricious in their exhibition, ranging from a paralysis of *all* the eye muscles, so-called total *ophthalmoplegia*; or attacking only all the external muscles of the eye, so-called *external ophthalmoplegia*; or perhaps only the sphincter pupillae and ciliary muscle, so-called *internal ophthalmoplegia*; or only paired ocular muscles, such as the external rectus of one eye and the internal rectus of the other, so-called *associated* or *conjugate paralysis*. Two outstanding characteristics are usually conspicuous in the eye symptoms of epidemic encephalitis: (1) They are often temporary and evanescent in duration; erratic in course and behavior and exhibit unpredictable and unstable clinical vagaries as to onset, tenure, recurrence or permanency; (2) frequently they also manifest a "selective" tendency; for example, of a group of ocular muscles supplied by the same nerve, only a few "selected" muscles—perhaps only one—of the group will be attacked. Various similar pareses and paralyzes also occur in syphilis, tabes, diphtheria, influenza, rheumatism, exposure to cold, various spinal and cerebral lesions, tuberculous meningitis, diabetes, toxic agents, ptomaine poisoning, etc., and these, therefore, must be excluded as etiologic factors. The presence of an Argyll Robertson pupil, for example, may be confusing. This pupillary phenomenon occurs quite regularly in tabes and syphilitic infection. Adler points out that if it be manifested in epidemic encephalitis it disappears rather promptly, while in syphilis it persists.

Pupillary disturbances, such as impaired reactions, inequalities, miosis, mydriasis, etc., occurring in epidemic en-

cephalitis are, as a rule, evanescent, vacillating, frequently disappearing quite promptly and perhaps recurring. In contrast, such phenomena occurring in spinal and other cerebral lesions are more stable, constant and persistent. The motor ocular nerves, notably the third and sixth, less commonly the fourth, usually bear the brunt of the ocular invasion and produce such symptoms as disturbance involving pupillary reaction, its form, size, etc.; accommodative impairment; restriction of ocular and lid excursion; diplopia, ptosis, etc.

It is customary to refer to so-called early and late symptoms. Among the symptoms which are frequently referred to as early ocular manifestations are ophthalmoparesis, which Stevens states occurs in 75 per cent of the cases; the extrinsic muscles of the eye are affected more frequently than the internal. Moore states that of 168 cases reported by the London Government Board, in 20 per cent diplopia was an early manifestation; the symptom disappeared rapidly as the disease evolved. Late ocular symptoms, those associated with the so-called residual or of the postencephalic parkinsonian stage, are blepharospasm, nystagmus, convergence, paralysis, anisocoria, oculogyric crisis, myostatic rigidity of the eyes.

The oculogyric crisis symptom as referred to by Williamson-Noble, "consists of spasmodic attacks of conjugate deviation of the eyes, most frequently vertical and often associated with a marked emotional factor. It is apt to be regarded as a manifestation of hysteria." The myostatic rigidity of the eye symptom, so named by Cords but first referred to by Nonne, is described by Barlow as follows: "The face has a masked-like appearance, the action of the facial muscles appears to be entirely abolished, and there is not a trace of mimicry in the face, the eyes are expressionless and stare vacantly into space or at some fixed object for many minutes and even hours at a time. Stellwag's sign is also present. It is not a question of paralysis of the eye muscle in these cases; when the patient is aroused the eyes can be moved with an effort, but they soon assume the same fixed position." It is generally accepted that optic neuritis, papilledema or fundus

changes are infrequent manifestations. Foster Moore believes that ptosis is the most common symptom; it is usually bilateral.

Practical Eye Diagnostic Summary.—An eye investigation should be included in the general examination of suspected cases.

It should be particularly directed to the lid and globe movement, the appearance of the pupil and the pupillary reactions, the accommodative and convergence range and an inspection of the eyegrounds.

DIABETES

The ocular manifestations of diabetes are many and varied, involving the lens, optic nerve, choked disk, retrobulbar neuritis, retina, choroid, ciliary body, vitreous, external ocular muscles, the accommodation and refraction. The incidence of ocular involvement in the disease is reported as from 20 to 33 per cent (Knapp). Groenouw classifies the eye lesions in order of frequency as follows: Cataract 30 per cent; retinitis 23.5 per cent; optic neuritis 5.7 per cent; ocular muscle disturbance 3.9 per cent. Other manifestations occurring are refractive changes (including accommodation), vitreous opacities, iritis, thrombosis of retinal vein, hemorrhagic glaucoma and optic atrophy. Of these ocular symptoms those most commonly met with in diabetes are *disturbances of vision accommodation and refraction, cataract, retinitis, and retinal hemorrhages*. Hirschberg states that the most common ocular manifestation is a contraction of the range of accommodation. DeSchweinitz believes that premature presbyopia with failure to accommodate is a common and early symptom. Changes in refraction, an increase of hypermetropia or the development of myopia, also occur. Inability to see clearly at the reading distance is common. Disturbances of vision, particularly near vision, and the necessity for frequent changes of glasses is, therefore, suggestive of a diabetic ocular invasion. Visual impairment is of frequent occurrence and in general is said to be more accentuated in diabetes than in albuminuria. The degree of impairment is dependent upon the extent and the distribution of the fundus changes. Fletcher states that "of the ocular complications cataract is the com-

monest." Stevens observes "Cataract usually of the soft variety and bilateral occurs in about 5 per cent of cases; it may be present in diabetics young or old." Two types of cataract occur in diabetes; one in young patients which is characterized by a rapid onset and development, and the other in the old which evolves gradually. Foster remarks that, "when a young person develops in both eyes within a few weeks from no known cause, cataracts which are evenly developed and when complete, may be seen by oblique illumination to be bluish white with sectors radiating from the center that have a luster like that of mother-of-pearl, an examination of his urine will almost certainly reveal that he has diabetes melitus."

Fuchs' view is that "the prognosis of diabetic cataract, as far as the operation upon it is concerned, is less favorable than in senile cataracts, because in diabetes wounds show less resistance to infection and moreover diabetes predisposes to iritis." Most observers are in agreement with this view and urge that before operation be undertaken the diabetic process should be reduced to the minimum and the patient's physical condition improved to the utmost.

Diabetic Retinitis.—Some difficulty may be experienced in properly evaluating the retinal changes due to an arteriosclerotic or albuminuric pathology which may coexist with the diabetes. It is generally regarded that diabetic retinitis is not of frequent occurrence; that it is bilateral; that it affects mostly older subjects and that it is a late manifestation of diabetes. DeSchweinitz mentions that in any case of diabetes of long duration, retinitis is seldom absent although it may sometimes be difficult to find the lesions because they may exist in the periphery of the eyeground and especially so if the complication of high myopia or cataractous lens is present. Moore states that retinitis affects older people only and that it does not occur under the age of thirty-five. Fuchs thus describes the retinal picture: "It is characterized in many cases by the presence of small, brilliantly white spots in the retina which chiefly occupy the region of the macula lutea and

its vicinity, without, however, presenting a stellate arrangement as in albuminuric retinitis. Sometimes by the confluence of small dots one or two large patches are formed which show by their crenated borders that they are composed of smaller dots. Between the white patches lie punctate extravasations of blood. The rest of the retina is transparent and the papilla too is unaltered. In other cases this characteristic picture is not present; in fact, diabetic retinitis may actually appear

Fig. 154b.—Diabetic retinitis. Extensive white exudations in the macular region. (deSchweinitz, "Diseases of the Eye.")

under the guise typical of albuminuric retinitis or closely resemble a retinitis circinata. Very rarely in young diabetics, especially when nearing death, *retinal lipemia* is found, *i.e.*, a condition in which on account of fat in the blood the retinal vessels appear reddish-white or pure white." Moore calls attention to some special features which he regards as particularly suggestive of a diabetic retinitis: (a) The patches of retinal exudate in diabetes tend to have sharp cut edges,

are often solid and soapy or waxy looking, are usually distributed in an irregular manner and sometimes form an irregular ring well wide of the macula; (b) a star figure is uncommon and if present it does not acquire the degree of symmetry that may be seen in renal cases; (c) the soft edged cotton wool patches so frequent in severe renal cases do not appear in diabetes; retinal edema is never so marked and thus retinal detachment does not result; (d) retinal hemorrhages are generally in the deeper retinal layers and, therefore, are roughly circular in outline instead of being flame shaped; (e) the circular retinal pigment spots which are not rare in the later stages of retinal retinitis are not seen in diabetes.

Hirschberg describes a retinal picture called central punctate diabetic retinitis which he also regards as characteristic of diabetic retinitis. The optic disk is normal and the retinal vessels are not visibly sclerosed. There is no hyperemia or edematous clouding of the surrounding retina. In the zone adjacent to the optic nerve between the superior and inferior temporal blood vessels groups of punctate, small, discrete, sharply defined white spots are seen. Between the spots numerous small punctate or striated hemorrhages are found. The spots may extend to the nasal side. Thorington observes that "the snow bank about the disk and the macular star, commonly seen in albuminuric retinitis, are absent in diabetes."

Hemorrhages.—Hirschberg (quoted by Knapp) divides retinal hemorrhages in diabetes into four groups: (1) Small punctate hemorrhages; (2) larger hemorrhages with vitreous opacities; (3) hemorrhagic infarct of the retina; (4) hemorrhagic glaucoma. It is believed that diabetic subjects are prone to develop intraocular hemorrhages and that a diabetic retinitis exhibits more hemorrhages than the albuminuric retinitis. They are small and since their seat is below the nerve fiber layer their outline is more or less circular and not, as in albuminuric retinitis, flame shaped due to the location of the latter in the nerve fiber retinal layer. Small dotlike retinal hemorrhages point to a diabetic condition. The hemorrhages may be limited or extensive and vitreous opacities may result

from a leakage of blood into the vitreous. Rarely hemorrhagic glaucoma may similarly be set up. Iritis is uncommon. Retrobulbar neuritis may occur with a relative central scotoma. The prognosis for life in a well marked diabetic retinitis is to be regarded as unfavorable though somewhat better than that of an arteriosclerotic or albuminuric retinitis. The visual prognosis likewise is uncertain.

Practical Eye Diagnostic Summary.—In all cases of suspected diabetes an examination of the eyegrounds should be made. The fundus changes are small, brilliantly white spots in the macular area and retinal hemorrhages. The picture may resemble an albuminuric retinitis. Usually the retina and disk present no changes. Suggestive symptoms are disturbance of vision, particularly near vision and the necessity for frequent change of glasses. Cataract is a frequent complication. The rapid development of a cataract in both eyes in young subjects is suggestive of the presence of diabetes mellitus.

NEPHRITIS

In May, 1933 a patient aged forty-five consulted me for reading glasses. His general physical condition he regarded as excellent. He presented no external evidence of ocular difficulty. His vision was practically normal and his only ocular complaint was of slight difficulty in reading the telephone directory. Examination of the eyegrounds disclosed an albuminuric retinitis and on subsequent general examination the diagnosis of Bright's disease was made.

The value of eye symptoms in nephritis is unquestioned. Clinicians generally emphasize their importance in contributing to the diagnosis and more especially in predicting a prognosis. It is a common experience for ophthalmologists to discover first eye pathology, suggestive or perhaps determining nephritis in patients who had regarded themselves as being in good condition. These facts are so well recognized that an examination of a case of nephritis cannot be regarded as complete unless an eye investigation has been included. The list of eye symptoms which have been attributed to nephritis is an extensive one. The most important may be summarized as follows: Noninflammatory edema of the eyelids, usually bilateral and involving, as a rule, the lower lids; spontaneous subconjunctival hemorrhage, especially of the recurring type, occurring in elderly people; chemosis of the conjunctiva; epi-

scleritis; exophthalmos; diplopia; vitreous hemorrhages; albuminuric retinitis; retinal hemorrhages; retinal detachment; hyperemia of papilla; optic neuritis; papillitis; choked disk; optic atrophy; visual field changes; impairment of vision to blindness.

Of these the most important is *albuminuric retinitis* which is said to occur in 33 per cent of cases. It is exhibited most

Fig. 154c.—Albuminuric retinitis; star-shaped figure in the macula; the circulation in the distended veins impeded where the latter are crossed by the arteries which are undergoing sclerotic changes. (deSchweinitz, "Diseases of the Eye.")

frequently in the small contracted kidney; next, in the chronic diffuse parenchymatous; next in the acute parenchymatous (scarlatina, etc.) and least in the amyloid degeneration. It involves specially the optic nerve and papilla, the macular region, the retina and the retinal vessels. The outstanding features of albuminuric retinitis of the typical type disclosed by

ophthalmoscopic examination are white spots in the region of the macula; these may take on the aspect of lines radiating from the fovea, but not necessarily invading it. Ultimately as a rule, these spots completely surround the macular region forming the so-called "star figure." The disk is encircled in toto or partially by round white or yellowish-white masses which resemble snow. Hence the name given them of "snow bank"; retinal hemorrhages occur either minute or of greater extent, irregularly distributed and assuming round linear or flame-shaped forms. The retinal vessels may or may not be obscured in areas by these and the vessels often exhibit changes characteristic of arteriosclerosis previously referred to. The retina is swollen, edematous and in areas, as a result, where these changes are marked it is opaque. The optic papilla is commonly involved, varying in degree from hyperemia and neuritis to well marked choked disk. Optic atrophy may eventuate as a sequel. These various changes are associated with two pathologic forms, the *inflammatory* or *exudative*, or the *degenerative*. Either of these types may be exhibited alone or in combination. Depending upon the dominance of the several lesions the appearances, according to Gowers, may be designated as degenerative, hemorrhagic, inflammatory or neuritic. The eye involvement is almost always bilateral. Vision is affected, varying in degree from slight impairment to blindness, depending upon the severity, the stage, the character, location and extent of the fundus lesions. Some degree of permanent impairment of vision is, as a rule, to be anticipated. Retinal detachment may occur and is of serious import from the visual standpoint, the prognosis for reattachment being uncertain. Occurring in the nephritis of pregnancy the prognosis is, however, more favorable. The prognostic value of albuminuric retinitis is of outstanding importance. There is a unanimity of opinion among clinicians that a well marked albuminuric retinitis in association with nephritis portends a tenure of life, in approximately 90 per cent of cases, not exceeding two years. Some reservations as to the interpretation of the eye findings in albuminuric

scleritis; exophthalmos; diplopia; vitreous hemorrhages; albuminuric retinitis; retinal hemorrhages; retinal detachment; hyperemia of papilla; optic neuritis; papillitis; choked disk; optic atrophy; visual field changes; impairment of vision to blindness.

Of these the most important is *albuminuric retinitis* which is said to occur in 33 per cent of cases. It is exhibited most

frequently in the small contracted kidney; next, in the chronic diffuse parenchymatous; next in the acute parenchymatous (scarlatina, etc.) and least in the amyloid degeneration. It involves specially the optic nerve and papilla, the macular region, the retina and the retinal vessels. The outstanding features of albuminuric retinitis of the typical type disclosed by

ophthalmoscopic examination are white spots in the region of the macula; these may take on the aspect of lines radiating from the fovea, but not necessarily invading it. Ultimately as a rule, these spots completely surround the macular region forming the so-called "star figure." The disk is encircled in toto or partially by round white or yellowish-white masses which resemble snow. Hence the name given them of "snow bank"; retinal hemorrhages occur either minute or of greater extent, irregularly distributed and assuming round linear or flame-shaped forms. The retinal vessels may or may not be obscured in areas by these and the vessels often exhibit changes characteristic of arteriosclerosis previously referred to. The retina is swollen, edematous and in areas, as a result, where these changes are marked it is opaque. The optic papilla is commonly involved, varying in degree from hyperemia and neuritis to well marked choked disk. Optic atrophy may eventuate as a sequel. These various changes are associated with two pathologic forms, the *inflammatory* or *exudative*, or the *degenerative*. Either of these types may be exhibited alone or in combination. Depending upon the dominance of the several lesions the appearances, according to Gowers, may be designated as degenerative, hemorrhagic, inflammatory or neuritic. The eye involvement is almost always bilateral. Vision is affected, varying in degree from slight impairment to blindness, depending upon the severity, the stage, the character, location and extent of the fundus lesions. Some degree of permanent impairment of vision is, as a rule, to be anticipated. Retinal detachment may occur and is of serious import from the visual standpoint, the prognosis for reattachment being uncertain. Occurring in the nephritis of pregnancy the prognosis is, however, more favorable. The prognostic value of albuminuric retinitis is of outstanding importance. There is a unanimity of opinion among clinicians that a well marked albuminuric retinitis in association with nephritis portends a tenure of life, in approximately 90 per cent of cases, not exceeding two years. Some reservations as to the interpretation of the eye findings in albuminuric

retinitis are important to note. The ophthalmoscopic picture, for example, as Foster points out, is not determining in establishing either the variety of renal lesion or the stage of the disease. Neither is the "star figure" exclusively a sign, since it may be found also in retinal arteriosclerosis, diabetes, brain tumor, lead poisoning and acute infectious diseases, in changes affecting the optic nerve, the papilla and in choked disk, pernicious anemia and leukemia.

Practical Eye Diagnostic Summary.—An examination of a case of nephritis without an inspection of the eyegrounds is incomplete. The eye findings, both diagnostically and prognostically, are too important to be ignored. The outstanding change to be looked for with the ophthalmoscope is the so-called "albuminuric retinitis," the characteristic changes of which are the star-shaped figure around the macula, the "snow banks" about the disk, retinal hemorrhages, edematous retina and involvement of the disk as an optic neuritis or possibly choked disk.

If time permitted many other general conditions which more or less regularly exhibit eye symptoms might be discussed in detail. Among these are the following:

HEAD INJURIES AND SKULL FRACTURES

It is of the greatest importance in these cases to ascertain the state of the intracranial pressure. Such knowledge may safeguard the patient against compression of the medulla and be the deciding factor in operative decision. An increase of intracranial pressure is often manifested by an optic neuritis, choked disk or various pupillary symptoms. In all head injuries and skull fractures, therefore, an examination of the eyegrounds should be made and repeated at frequent intervals.

TABES

Eye symptoms are almost a regular accompaniment of tabes and are of definite value in establishing the diagnosis. The chief eye symptoms are Argyll Robertson pupil, which observers estimate occurs in 76 per cent of cases, often as an early symptom; optic atrophy in approximately 20 per cent of cases, also often an early symptom; ocular palsies and alterations in the visual fields, particularly those for color.

SYPHILIS

All the structures of the eye, with the exception of the lens, may be affected by syphilis in any of its stages. The uveal tract—iris, ciliary body, choroid—are the structures most commonly involved. Both eyes are ultimately affected. A practical clinical observation is that in all eye diseases which prove intractable to treatment the possibility of syphilis being a factor should be excluded.

PITUITARY BODY

Anatomically, the relation of the pituitary body to the optic chiasm is exceedingly intimate and in consequence eye symptoms are frequent and often a determining manifestation. Changes in the visual fields, producing the various types of hemianopsia, are of special significance. Amblyopia, exophthalmos, pupillary phenomena, and nystagmus are also encountered. In a suspected case of pituitary disease a visual field should always be taken.

From the foregoing brief résumé of the subject, *The Value of Eye Symptoms in the Diagnosis of General Disease*, the following conclusions are warranted:

1. A very considerable number of general diseases exhibit eye symptoms during their clinical evolution and these eye symptoms are frequently of value as an aid to diagnosis and prognosis.
2. An eye investigation should be included as a routine measure in general physical examination. The details of such an examination are relatively neither excessively time consuming nor unduly technical and are definitely within the scope of the general physician.
3. Training in the use of the ophthalmoscope and the details of ophthalmologic examination in the study of general disease should be stressed and routinely applied in undergraduate teaching.

CLINIC OF DR. MICHAEL HIGGINS EBERT

COOK COUNTY HOSPITAL

RINGWORM OF THE SCALP

Case I.—This boy of six is brought in by his mother because she has noticed "bald spots" in his scalp. The first of these appeared four weeks ago and now is as large as a silver dollar. The later ones are smaller. On questioning her we learned that a younger child in the family also has one or two similar spots. The disorder causes the child no discomfort. On examining the scalp we find that the involved areas are circular, coin sized, and not completely bald (Fig. 155). There are a few stumps and stubs of

Fig 155.—Ringworm of the scalp due to *Microsporon audouinii*.

hair remaining which can easily be epilated. The whole area is covered with a fine grayish scale. Had the mother used some home remedies, the scale might well have been absent. We pull out several hair stumps and place them on a glass slide, cover them with a coverslip and allow a few drops of 15 to 20 per cent potassium hydroxide solution to flow under the slip. The preparation is then set aside to be examined after an hour or two. A similar

preparation is made from the scales which are scraped off the scalp and placed on another slide. The potassium hydroxide solution softens the horny material in the hair and epidermal scales, and clears them so that fungus spores and mycelia become visible.

While the material is softening we will discuss the differential diagnosis of this case. Alopecia areata is not uncommon in children. It produces well defined circular areas of baldness which occur erratically in the scalp. If the scalp has not been treated, the baldness is complete in the affected areas when the lesion is recent. The surface is white, shiny, but not atrophic. If the process is active, short hairs, about $\frac{1}{4}$ inch long, are found near the active margin which look like exclamation points. These hairs are nearly normal in caliber and color distally, but near the scalp are fine and atrophic. This gives them the appearance of an exclamation point. However, if the bald spot be of some duration, fine, new lanugo hairs may have regrown, giving it a fuzzy appearance. If the scalp has been treated with strong ointments or other preparations, a secondary dermatitis may result in the affected patches, making the diagnosis more difficult. The essential features are still present and there is no history of other members of the family being similarly affected.

Discoid lupus erythematosus may produce round bald patches in the scalp. These are dull red and may or may not be scaly. The follicular openings are dilated, and other similar plaques are usually found present in the ears or on the face of the patient. The patches heal with atrophic scars which result in a permanent loss of hair in the area. Lupus erythematosus in a child of this age would be unusual.

Now let us examine our preparations, first with the lower power of the compound microscope, cutting down the light to a minimum. We find that the proximal portion of the hair root is covered with a sleeve which is made up of a mosaic of thousands of tiny spores set closely together. Under the high dry magnification we find these spores look like little circles. The scales are next examined and are found to contain branching fungus mycelia. This is the characteristic

picture of a microsporon infection. The procedure I have described is not a difficult one. Anyone capable of ordinary work with the microscope can easily demonstrate ringworm fungi. Do not be in a hurry. Do not heat the preparations. Allow plenty of time to elapse before making the final examination. Examine several specimens. One should not make a diagnosis of ringworm of the scalp with its attendant social isolation without the microscopic demonstration of the fungus, any more than he would diagnose tuberculosis without demonstrating the bacillus.

The majority of microsporon causing lesions similar to the ones we have seen today are classified as *Microsporon audouini*. Dr. Gruby, a Viennese who had migrated to Paris, first described this organism in 1844 and named it in honor of a famous French botanist. Exact species determination can be made only by an experienced mycologist by culture on various artificial media.

Occasionally we see cases of this type due to *microsporon lanosum*. This is a fungus of animal origin (cats, dogs, horses, etc.). It usually sets up a little more inflammatory reaction and is more susceptible to local treatment. This variety may attack the glabrous skin outside the scalp or even the beard region in adults.

Each one of these tiny spores has an extremely resistant membrane. Chemicals kill it with great difficulty. It is carried with the scales in the combings from the scalp. It adheres to the inside of the head dress and to the bed linen. If it finally arrives on another child's head, it germinates, sends out mycelia which penetrate the mouth of the hair follicle, grow around the hair root, penetrate the cuticle and finally produce a new crop of spores. You are all well aware that this is an extremely infectious disease. In institutions like orphan asylums, boarding schools, etc., it spreads like wildfire. It is so contagious that formerly special schools were set aside for its victims. It is a real problem even for the sporadic case, for he must be excluded from school just at an age when formal training is indispensable. It may even flare

up in great epidemics like the one in Basle, Switzerland, after the World War. Fortunately, the disease is self-limiting. Shortly after puberty, due to the action of the endocrine glands, a subtle change takes place in the hair and the sebaceous secretions which oil it, so that they are no longer a fit habitat for the *Microsporon audouini*. Thus, a disease which was extremely difficult to eradicate now disappears spontaneously.

Treatment.—Two factors conspire to render the treatment of ringworm of the scalp very difficult. First, the fungus proliferates deep in the hair follicles where it cannot be reached by ordinary measures. Second, the fungus spores are extremely resistant to parasitocides in a strength tolerated by the human skin. They can live long periods in dried material and still remain viable. The first difficulty is overcome by temporary epilation, the second by scrupulous cleanliness, keeping the scalp clipped short or better shaved, and by the use of antiseptics which will prevent germination of the spores.

The most effective agent for temporary epilation is the x-ray. This should not be immediately used in every case, however. Fortunately, practically all the forms of ringworm of the scalp with the exception of *Microsporon audouini* respond to topical applications. If absolute species determination by a competent mycologist is not possible, local treatment should be given a thorough trial.

If local measures are to be attempted, any crusts which are present should be first softened by boric acid wet dressings and olive oil, and then removed. The hair should be clipped very short or shaved and washed thoroughly at least once a day with soap and water. The hair may then be epilated in a zone $\frac{1}{2}$ inch wide about the affected patches with a tweezers or, better still, with a pencil made of pitch. An ointment is freshly prepared by adding 1 drachm of iodine crystals to 1 ounce of goose grease. This is rubbed well into the affected areas and surrounding zone every night. In the morning an ointment of 3 per cent salicylic acid and 5 per cent ammoniated mercury is applied to the entire scalp. The reac-

tion which occurs is a desirable one for it raises the tissue resistance to the fungus infection. However, we may have to abstain from the use of the iodine ointment when the reaction occurs and possibly use a boric acid wet dressing twice a day. The other milder ointment can usually be continued. As soon as the reaction subsides we resume the iodine ointment.

Whatever local application be used, frequent microscopic examinations of the scales and hair stumps must be made to check on the presence of the fungus. After all signs of fungus infection have been absent on repeated examination, the iodine ointment may be discontinued, but a 5 per cent ammoniated mercury ointment or 5 per cent sulphur ointment should be continued as well as the shaving and washing for two months, and repeated occasionally for short periods several months thereafter.

Darier, of Paris, recommends washing the scalp daily, drying it and then painting the whole scalp with a mixture of tincture of iodine 1 part and alcohol 3 parts, this painting to be continued daily or every other day depending on the amount of reaction.

Parkhurst, of Toledo, suggested a régime which has been found highly successful. He keeps the scalp closely shaven, washes it night and morning with soap and water, preferably tincture of green soap. He applies at night an ointment prepared freshly with 10 per cent fresh saturated alcoholic solution of iodine crystals in goose grease. In the morning he applies a salve made up as follows:

Thymol	...	2 to 6 per cent
Ammoniated mercury	..	3 to 6 per cent
Salicylic acid	.	2 to 4 per cent
In benzoinated lard		

The strength of the active ingredients is gradually increased to the point of tolerance. This ointment is applied to the entire scalp.

During the treatment all the toilet articles should be kept separate and rigorously cleansed. The child should wear a

paper cap inside of his usual headdress and a similar one at night. These should be burned after a single wearing. Until the disease is well under control the child should not play with other children. Where there are several children in a family these should be frequently examined to detect incipient cases. Patience and scrupulous care are the most essential factors in the treatment.

If the infection proves intractable to these measures or if the hygienic environment is such that proper treatment of the patient and prophylaxis of other children is impracticable, arrangement should be made for x-ray epilation. Stimulating preparations should be discontinued for at least a week. The epilation should be done only by a physician who is adequately trained and has had plenty of experience. The amount of x-ray which produces a temporary alopecia is so near the amount which produces a permanent alopecia that one should no more attempt this procedure without special training than he would attempt a thyroidectomy without surgical apprenticeship. When properly performed, the hair begins to fall two weeks after the exposure and begins to regrow about one month later. The scalp should be washed carefully every day with soap and water until the fall is complete. Then it should be bathed daily with a 1:5000 solution of bichloride of mercury in 50 per cent alcohol, and a 5 per cent ammoniated mercury or sulphur ointment used daily for two weeks. Later this may be increased to a 10 per cent ointment. The scalp should be watched carefully for reinfection. The local treatment should be continued for several months.

The internal administration of thallium acetate will produce temporary alopecia of the scalp hair. The therapeutic dose is so close to the toxic dose that we are not warranted, I believe, in recommending this measure to the physician. The toxicity increases with the age of the child. In children near puberty the effective dose is almost always dangerous.

Case II.—Our next patient is a boy of nine, who presents what appears to be a large flat carbuncle on the scalp (Fig. 156). This has been present for three weeks and is tender and somewhat painful. The lesion is well defined,

the size of a silver dollar, raised well above the surface of the scalp. Its surface is dull red in color, knobby, and feels boggy. Through numerous openings a gelatinous material exudes. A few stumps of hair remain in the surface of the lesion but can easily be epilated. At first glance it will appear that if this lesion were laid wide open with a scalpel it would quickly drain and heal. However, appearances in this instance are very deceptive. This boggy mass is due to another type of ringworm infection, a trichophyton. The particular variety is of animal origin (ectothrix). Most ringworm infections of animal origin set up a considerable reaction in the affected skin. This reaction eventually kills the fungus so it is much harder to find the organism than it was in the first case where the *Microsporon audouini* has learned to

Fig. 156.—Kerion of the scalp.

live almost in symbiosis with the body cells, producing a minimum of reaction and persisting a maximum of time. If we examine several of the stumps of hairs we may find a branching mycelium in the hair shafts.

Treatment should consist of hot wet dressings of boric acid or magnesium sulphate. Follicular pustules may have to be opened to promote drainage. The area should be painted daily with tincture of iodine 1 part, 50 per cent alcohol 3 parts. A preliminary epilation of the surrounding hair is advisable as in *microsporon* infections.

Nonspecific protein injections in the form of typhoid vaccine may be used in addition to raise the patient's resistance.

A type of ringworm of the scalp rarely seen in Chicago but prominent in England and on the continent is the "black dot" or disseminated ringworm infection. It is easily missed unless the scalp is carefully examined for the lesions are small, inconspicuous and widely disseminated. They consist of scaling macules about a single hair follicle or a group of very few follicles. The affected hairs persist as stumps among their healthy neighbors. These stumps may turn on themselves, like a compressed corkscrew, beneath the scales or in the mouth of the follicle. Their appearance gives rise to the term "black dot." The majority of these cases is also due to a trichophyton but of the endothrix variety which is of human origin. Careful search of the stumps of hairs in a potassium hydroxide preparation will reveal the spores which are a little larger than those of *Microsporon audouini* and are enclosed within the hair shaft, are quadrangular in shape and arranged in lines. All cases of localized dandruff should be suspected, especially if any of the hairs are broken off, and a careful microscopic examination made for the fungus.

Ringworm of the scalp may occasionally produce a generalized eruption of a toxic character which is termed an "id" eruption. When the original site of the infection is irritated or inflamed by treatment or secondary infection, some of the spores or perhaps their toxic products get into the general circulation and are carried to the peripheral cutaneous vessels. The skin has become during the course of the disease allergic to the products of the fungus and now reacts with an acute transitory inflammation which destroys any spores that may be present. So search for them is usually fruitless.

In kerion of the scalp a trichophytid is not uncommon. It is follicular, may be lichenoid, papular or consist of scaly patches. It is symmetrically disseminated on the trunk and lasts only a few days or a few weeks or may recur. It may easily resemble measles or scarlet fever. Microsporids are less frequent in occurrence.

The types of ringworm we have discussed, except kerion, heal without scarring. There is another fungus infection of the scalp, fortunately seldom seen in this country, which lasts a lifetime, gradually destroys the hair follicles, leaving an irregular atrophic scar beset with a few remaining wisps of hair. This is favus, caused by *Achorion schoenleinii* (Fig. 157). When well developed and untreated it produces small sulphur-yellow cups at the base of the involved hairs, giving off an unpleasant odor. It may involve the glabrous skin and the nails. The patients that we see here, however, usually come in with irregular areas of permanent baldness. It is

Fig. 157.—Favus of the scalp.

only by careful search of the scales taken from the margin of the atrophic areas that the fungus can be demonstrated. Favus is fairly common in southern and eastern Europe. Immigration officials have attempted to prevent its entrance into the United States. Nearly all the cases we see are immigrants with an occasional native-born patient from an infected family. The disease is contagious and intractable to treatment. Since the patent-medicine vendors have coined the priceless term "athlete's foot," and made America ringworm conscious via the radio, we constantly hear people say that they have athlete's foot of the hands or athlete's foot of the crotch.

Let us not commit the absurdity of "athlete's foot of the scalp." The fungus which affects the foot can never be transferred to the scalp. So you can reassure unnecessarily disturbed parents who may confuse the terms and fear that they have infected innocent offspring with an organism originally picked up at a Turkish bath or golf club.

CLINIC OF DR. SIDNEY A. PORTIS

COOK COUNTY HOSPITAL

GASTRO-INTESTINAL MANIFESTATIONS OF SYSTEMIC DISEASE AND THEIR DIFFERENTIAL DIAGNOSIS*

THIS morning I would like to bring to you a group of cases that illustrate very clearly how one frequently might overlook some systemic disturbance because the patient complains of symptoms referable to the gastro-intestinal tract. I think I have sufficiently emphasized to you in past lectures the more or less pathognomonic features and symptom complexes related to pathology *per se* in the abdomen. With this background it might be well for us to see what other disturbances could give these same symptoms and yet an exhaustive gastro-intestinal examination give us little or no findings. I am sure you will agree with me that you cannot know gastro-enterology until you have learned general medicine. There are so many conditions outside of the abdomen that simulate intra-abdominal disease that it is only the exceedingly myopic physician who sees only in the light of intra-abdominal manifestations. Many patients are needlessly operated. Many patients are wrecked for their future life because some over-zealous physician has neglected to make a very painstaking and very thorough investigation of the patient as a whole. This not only includes a very careful detailed history with a searching physical examination, but also a very exhaustive laboratory and x-ray study. Before one can conclude that the pathology is in the gastro-intestinal tract and that it alone accounts for the symptoms, you must exclude beyond all rea-

* Clinic given for students of Loyola University Medical School.

sonable doubt any extra-abdominal disturbance which might cause the patient distress.

The first patient of this group of cases which I would like to present is a woman, forty-seven years of age, who consulted me on August 2, 1927 with a history in which her main complaints were belching, and a bitter taste in her mouth. The story is that she had a cholecystectomy and appendectomy nine months previously for the same complaints. No stones were found. For a short time following surgical intervention she was temporarily relieved, however, the same symptoms soon returned. She experienced fulness and distention particularly in the right upper quadrant, coming on at any time and lasting for a half hour, then disappearing spontaneously. She belches considerably and has noted a peculiar taste, not quite bitter, which as a rule comes on within a short time after meals. The distress is never present at night and disappears while resting. She complains of some aching across the back. Her appetite was normal. Her bowels were slightly constipated and she had occasional frequency of urination. The family history was of no importance. She had one pregnancy and no miscarriages. Menstrual history was regular up to the menopause at forty-four. Tonsils and adenoids had been removed at the age of forty, and the cholecystectomy and appendectomy done when she was forty-six.

Physical examination revealed a moderate enlargement of the thyroid gland. There was a coarse tremor of the hands and tongue. Reflexes were intact. Lungs were negative as was the heart. Blood pressure measured 102 systolic and 74 diastolic. There was some tenderness over the right rectus scar through which the gallbladder and appendix had been removed. There was some tenderness over the sigmoid region. The abdomen otherwise was essentially negative. Bimanual examination revealed moderate relaxation of the perineum, uterus anteфлекed and slightly enlarged, and some thickening in the region of the appendages.

Laboratory work revealed the urine containing an occasional pus cell but otherwise essentially negative. The stool showed some undigested food, a little mucus but otherwise was negative. There was no evidence of amebae or cysts. The stomach acidity was 10 free and total 30, with no evidence of obstruction. In the Ewald meal free acid was 35, total 45. Hemoglobin was 93, red count 5,000,000, and leukocytes 8200, with a normal differential count. Wassermann and Kahn tests were negative. The basal metabolism rate was -14.

Fluoroscopic examination of the chest and abdomen revealed the lungs essentially negative as were the heart and aorta. The stomach was normal and the duodenal bulb filled out normally. The stomach emptied in four hours. Subsequent observations on the bowel revealed normal passage through the colon of the barium given by mouth.

In this particular patient with her gastro-intestinal manifestations, with subsequent surgery for them without improve-

ment, a very exhaustive and intensive study failed to reveal any definite cause for her disturbance. One might be prone in this case to think that her symptoms were entirely functional. However, clinically the patient did not impress me as one who would be predisposed to functional disturbance. She seemed like an exceedingly stable individual. There was one curious fact that might have been overlooked in her clinical story and which was reemphasized on going over the picture with her. That was that when she had a desire to urinate it must be satisfied within a relatively short time. She did not emphasize or mention it in her first visit when her history was taken, but in her story she alluded to a urinary disturbance which was not of much importance to her. Following this line of thought, it suggested itself that the patient might be cystoscoped to see whether any pathology might be found in the urinary tract to explain the symptoms. Interesting as it may be, examination of the urethra revealed a firm, fibrous stricture 2.5 cm. long at the outlet. This was followed by a No. 24 F. Cystoscopic examination revealed a markedly trabeculated bladder, especially on the floor and posterior wall. Both ureteral orifices were normal and there was a moderate trigonal cystitis.

Curious as these findings may be, they are important as far as the patient it concerned because had they been recognized some time ago, useless surgery would have been prevented. Following adequate dilatation at repeated intervals, the patient's gastro-intestinal manifestations entirely disappeared. Her whole outlook on life was very much improved. She is now able to go about, doing her normal daily work, and has entirely forgotten that she has been ill. Yet, had not this patient's urinary tract been very carefully investigated she would have continued to go on from doctor to doctor, probably had more surgical intervention, and been no better off in the end. We were not justified in telling this particular patient that her urinary tract was cause of her symptoms until we had ruled out other causes in the intestinal tract which might account for her symptom complex. In a few

moments I will discuss with you why patients with genito-urinary disturbances give gastro-intestinal manifestations.

The next patient I would like to present is a young married woman of twenty-seven who consulted me on August 20, 1923, complaining of pain in the right side, nausea, lumbar pain, headaches, loss of weight, and a tendency to perspire easily. For the past five years she had pain in the right side which was more or less constant. Appendectomy four years previously for this complaint failed to relieve her symptoms. The pain radiated up into the back and to the right scapula. She felt nauseated when the pain was at its height. It was never referred to the pubic region and she never required opiates for relief. There was some belching and distention after meals.

The noteworthy physical findings were a systolic murmur at the base of the heart, a blood pressure of 142 systolic and 90 diastolic. There was some tenderness over the gallbladder region, and a mobile right kidney was observed. Subsequent gastro-intestinal roentgenograms revealed a prepyloric spasm on the lesser curvature of the stomach which was distinctly tender. Otherwise, the gastro-intestinal examination was essentially negative.

She was treated for a period of three years off and on under gastro-intestinal management, with improvement and relapses. At this time, with the advent of cholecystography the gallbladder was investigated and it was thought to be pathologic. However, her symptoms in general overshadowed the findings in the abdomen. It was thought wise to investigate the urinary tract, because of this mobile right kidney. So, in 1928 Dr. Herman L. Kretschmer reported the following:

"Cystoscopic examination was negative except for a freely movable right kidney. The pyclogram showed the right kidney pelvis in normal position with the patient lying flat on the table, and a prolapse of the pelvis down to the crest of the ilium with the patient sitting up. The kidney could be easily displaced, so that the pelvis could be seen over the spine."

After much discussion and with some reluctance on the part of the urologist it was decided to do a right nephropexy. This was subsequently done and for the last seven years the patient has been completely relieved of all her symptoms and has had no recurrence at all of her gastro-intestinal manifestations.

Another similar case to this only in a male, was that of a patient, aged forty-seven, who consulted me in 1929 complaining of abdominal distress, belching and distention. For the past year or more the patient had had regular, recurring periods of abdominal distress coming on about an hour after meals, especially after the intake of fried and greasy foods, associated with fulness, distention and excessive belching. The past history other than a herniotomy fourteen years before and an appendectomy eleven years before was essentially negative.

Physical examination revealed no noteworthy manifestations. Examination of the urine and stool was negative. The gastric content was normal. Roentgenological examination of the gastro-intestinal tract revealed normal stomach and duodenum. Cholecystogram revealed what appeared to be a

pathologic gallbladder. Subsequent gastro-intestinal management made little improvement in the patient's complaints.

During the course of observation a symptom of frequent and severe distress of the urinary tract developed. Cystoscopic examination was thought advisable. At this time there was revealed a residual bladder urine of 3 ounces and normal bladder tolerance. There were slight, coarse trabeculations on the posterior wall of the bladder, normal ureteral orifices, a depressed trigone with median lobe enlargement, which was definitely elevated and hypertrophied, but with lateral lobes within the limits of normal.

Following transurethral resection of the prostate the gastro-intestinal symptoms have completely disappeared.

Is it any wonder then that gastro-enterologists might become urologically minded occasionally and search at times in the urinary tract for a possible explanation of the gastro-intestinal manifestations? I do not want to leave you with the feeling that this may be a panacea for all gastro-intestinal disturbances, but there is a certain group of these patients which often will continue to be overlooked unless this possibility is sufficiently brought home to them either through their personal experience or by listening to the advice of those who have had trials and tribulations in cases of this sort.

Why should urological diseases give gastro-intestinal manifestations? E. C. Smith in an article some time ago very carefully showed that there was a very definite interrelation of the nerve supply of the upper urinary tract with the organs of digestion. He maintained that since both are supplied by the vagus and sympathetic nerves, any disturbance of the kidney may be reflected through the gastro-intestinal tract. The connecting link is through the celiac ganglion. Therefore, it is reasonable to suppose that impulses originating in the urinary tract can produce gastro-intestinal symptoms without pathologic changes.

The next patient I would like to present is a young lady, twenty-seven years of age, who came in because of pains in the lower abdomen, "dyspepsia," and frequency of urination. Since 1933 the patient has complained of marked frequency and urgency of urination, sometimes urinating as much as six to eight times at night. There was no evidence of any hematuria or pyuria. During this time she has complained of indigestion, consisting of heaviness and a feeling of distention in the epigastrium occurring about fifteen minutes after meals, occasionally relieved by alkalis, associated with much belching.

and heart burn, particularly after greasy foods. She had been somewhat constipated. There had been occasional nausea but no vomiting, and no hematemesis. She gained in weight. She is very irritable, has crying spells, some vertigo and faints frequently.

Physical examination other than slight tenderness over the region of the gallbladder and appendix is essentially negative. The other noteworthy findings are the absence of a corneal and pharyngeal reflex. Bimanual examination was negative.

The urine and stool were essentially negative. Stomach acids were 68 free and 80 total; with Ewald meal 90 free and 100 total. There was no evidence of retention. The blood showed evidence of a secondary anemia with a normal differential. The Wassermann and Kahn were negative. The basal metabolic rate was - 6.

Fluoroscopy of her chest revealed no unusual findings. Stomach was prolapsed into the pelvis for a distance of 2 inches, but was otherwise negative. The duodenum showed a spasm on the greater curvature side at its middle. The second portion showed evidence of stasis and surging. It was curled upon itself and had an S-shaped arrangement. The stomach emptied at the end of four hours.

Subsequent observations at twenty-four and forty-eight hours revealed a definitely tender cecum. The appendix was not visualized and the bowel was moderately spastic.

Cholecystogram showed a normal gallbladder as far as function was concerned.

Chest stereograms revealed no unusual pathology.

Urological examination revealed external genitalia negative, the urethra slightly narrowed, and to quote the urologist her history is entirely inconsistent with the clinical findings. "I do not believe the slight stricture of the urethra which she has is the cause of her frequent urination." To amplify this latter statement, dilatation of the urethra failed to reveal any of the symptoms.

On suitable gastro-intestinal management and with corset and pad to hold up the stomach, no improvement was noted. Following this a course of hospitalization was advised, with elevation of the foot of the bed and the usual measures adopted for the treatment of visceroptotic individual.

Still there was no improvement. The pains in the abdomen were very migratory. It was then decided that possibly there might be some other cause or group of causes which might be accountable for her symptoms, but could not be demonstrated on the basis of organic findings. It is interesting to note that the girl was married at the age of nineteen, was married for three years and then separated for five years. She had three pregnancies, two interrupted and one child living and well. These periods of distress seemed to be definitely related to her sexual habits. Realizing that this might be a basis for her symptom complex, an analytic study was made. It is interesting to note that much of her gastro-intestinal symptoms are closely associated with her inhibited sexual desires. Under the guidance of a very competent analyst, the patient has made steady and definite improvement and much of her gastro-intestinal symptoms have entirely disappeared.

This particular type of a patient is one who usually shows a battle-scarred abdomen and is frequently opened up for surgical intervention at the least provocation. I call it to your attention this morning because there is altogether too large a group of these patients who are going around from physician to physician and from surgeon to surgeon in an attempt to cure their gastro-intestinal complaints, when a careful, painstaking analysis of their symptom complex with the associated findings might lead one to believe that there is a so-called functional basis for their complaints. However, you are not justified in concluding that the functional basis alone is a causative factor until you have made an exhaustive laboratory and x-ray study to rule out the presence or absence of organic pathology.

The next patient is a married woman, forty years of age, who came in because of a bowel distress. For several years she has noticed a tendency to loose stools. She has been told that she has colitis. She knows that if she avoids certain foods she is better. She has lost about 4 pounds in the last few months. She has also noticed some bleeding hemorrhoids. Her past history was that she had one brother and one sister die of pulmonary tuberculosis. She has had two children in the eleven years of married life, both living and well. She has had the usual childhood diseases. About a year and a half ago had a so-called "influenza" with some hemoptysis, and yet complains of no symptoms referable to her chest at the present time.

Physical examination showed some dullness on the right side of her chest, especially in the middle portion. There were numerous moist râles, "clicks." The heart was essentially negative. The liver was not palpable but the spleen extended 1 inch below the costal margin, not tender. There was some tenderness along the course of the colon. Bimanual examination showed no unusual findings. Rectal examination showed large external and internal hemorrhoids. The urine showed no noteworthy findings. The stool was essentially negative except that acid-fast bacilli were found. The stomach tests were within range of normal. Blood showed a secondary anemia of mild grade. Wassermann and Kahn were negative. Basal metabolism was -1 per cent. Her agglutination tests for bacillary dysentery organisms were negative as were the complement fixation tests for amebiasis. The sputum showed numerous acid-fast bacilli.

Stereograms of her chest revealed evidence of involvement of the right upper and middle lobes. No evidence of cavitation could be seen. Fluoroscopic examination of her stomach and duodenum was negative.

In this particular case the patient was complaining of evidence of a so-called "colitis" for several years, but more in the

last year. She had not lost any weight. There were no chest symptoms, yet one would be willing to believe that her gastro-intestinal symptoms were entirely related to her pulmonary tuberculosis. And since she has been under management at the sanatorium the more or less subacute manifestations of a tuberculous infection are subsiding, her gastro-intestinal symptoms are improving. No attention at all is paid to diet or to foods that formerly disturbed her so far as her so-called "colitis" is concerned.

Many patients with incipient, subacute, or even active tuberculosis show symptoms referable to the gastro-intestinal tract and it is only with a painstaking examination that these facts are brought to light, and in many cases pulmonary findings of this type are accountable for gastro-intestinal disturbance. When the pulmonary pathology becomes quiescent, symptoms referable to the abdomen entirely disappear.

Closely allied with this group of cases and very frequently mistaken in their diagnosis are a group of patients who have disturbances of the thyroid gland. Very frequently patients with symptoms of so-called "masked hyperthyroidism" present a gastro-intestinal picture which is so bizarre in nature and so prominent that the thyrotoxicosis is entirely in the background. This group of cases forms one of the very common sources of error in diagnosis of patients who consult me from time to time. Curious as it may be, it has not only been confined to young individuals but also is seen in elderly patients. Hyperirritability of the gastro-intestinal tract associated at times with hypermotility is a frequent cardinal symptom of this condition.

For instance, as we glance over the next patient, who is a married woman, fifty years of age, who comes in because of pain in the epigastrium and who states that for the last eleven years she has had dull pains in the epigastrium which had no relation to foods. She vomits frequently five to ten minutes after meals, which only slightly relieves her distress. Five and one-half years previously a cholecystectomy was performed for the same symptoms, with only transient relief. She has a great deal of nausea and some belching. Food taking only partially relieves her distress. There is no particular seasonal variation to her discomfort. Three years ago she had an appendectomy, but this gave her no relief. She has been gradually losing weight.

In her past history she had her menopause at thirty-nine. She had six pregnancies, three children living and well. She occasionally got up at night to urinate. Her appetite was poor, due to distress when eating, and there was some tendency to constipation.

Physical examination revealed a moderately obese woman. Thyroid was just barely palpable. The eye muscles only showed a slight weakness. There was a coarse tremor of hands and tongue. The reflexes were intact. The lungs were essentially negative. A systolic murmur was heard over base of heart. Blood pressure measures 150/70.

The abdomen showed numerous scars. There was a large hernia where the appendix had been removed.

Examination of urine and stool revealed nothing unusual. Her stomach acids were absent and 10 free in motor meal, with no evidence of retention, and 20 free and 25 total in the Ewald meal.

Fluoroscopic of her chest and abdomen revealed a large shadow in the substernal region resembling a thyroid. The lungs were essentially negative. The heart was slightly enlarged in the transverse diameter. The stomach was negative. The duodenal bulb filled out normally.

Her Wassermann test was negative and her blood showed a slight secondary anemia. Her basal metabolism was + 62 per cent.

In this particular case no mention was made at all of nervousness, irritability and palpitation and all the symptoms that usually go along with ordinary thyrotoxicosis, and yet over a period of years this lady has had a low grade thyroid disturbance, with gastro-intestinal manifestation, subsequent surgical interference with no relief. We find on repeated metabolism tests the this is an out and out case of thyrotoxicosis.

Particularly interesting is it that she has a substernal thyroid. Following a subtotal thyroidectomy the patient was completely relieved of her gastro-intestinal symptoms, and for the last three or four years has been very comfortable.

If we look at the opposite picture it brings to mind a patient, who is seventy-eight years of age, who was complaining of gastro-intestinal symptoms, accompanied by pain, discomfort and obstinate constipation. She gives a history of the last fifty to sixty years of persistently taking cathartics with only partial relief. Very exhaustive examinations in the past had yielded no results. She was told by a doctor that she had a carcinoma of the stomach. However, one observation of this patient, a very fat, myxedematous type of individual who had apparently lost no weight, would immediately give you the inference that possibly she was over a period of years a hypothyroid individual. Exhaustive examination of her gastro-intestinal tract revealed no evidence of malignancy, and no cause for her long-standing constipation. Her

basal metabolism was — 25, and nothing more was done for this patient than to put her on small doses of thyroid three times a day. No particular attention was paid to diet. The patient is now eighty-three years of age, still continues to take her small doses of thyroid extract and has a daily bowel movement.

Oh, how frequently are patients treated for years and years for constipation, if the clinician would only be alert to know that hyperthyroidism is a very common etiologic factor in producing the so-called "picture of constipation." You are not to believe that hypothyroidism is particularly confined to only obese individuals. It is frequently found in individuals who have normal weight or even weight below their standards. Both these disturbances of the thyroid gland give gastro-intestinal manifestations and yet as far as organic pathology of the gastro-intestinal tract is concerned, it is entirely lacking.

Just the other day, there entered my ward service a patient, some fifty years of age, who had lost some weight and who had been treated for a period of months for gallbladder disease because he had associated nausea, vomiting, some belching, and some fulness after meals. The one symptom which the clinician did not pay enough attention to was, that this patient had persistent headache, and furthermore associated with these headaches he had a slight auditory disturbance on the right side. While I am perfectly willing to admit that headaches may be a common symptom of gastro-intestinal disease, I would like to emphasize that the persistence of headaches after the presumed gastro-intestinal disturbance has been under control, should lead you to suspect the possibility of some other cause for the headaches. Two outstanding conditions come to mind, one the possibility of a cerebral neoplasm and the other, a so-called "indurative headache" associated with a hypertrophic osteo-arthritis of the cervical spine. In this particular patient subsequent neurological examination and ventriculograms revealed that the patient had a neoplasm at the cerebellopontile angle. The patient died before operative interference could be done. Necropsy examination revealed a tumor at the cerebellopontile angle.

This is not an uncommon source of error in gastro-intestinal diagnosis and it only goes to reemphasize to you the need of careful observations in each patient as to the cause of their particular complaints.

And how often is the clinician taken off his guard by such a patient as follows:

A young woman, twenty-five years of age, who complained of headaches, nausea and constipation. Patient said she first began to notice constipation ten months ago during pregnancy. Constipation continued through the period of gestation and was later relieved. She states that she had headaches which involved the entire head and were much more constantly present in exacerbations and remissions. These sometimes keep her awake at night, and they are so severe that she sometimes becomes nauseated and faints, and has blurred vision and black spots before her eyes. Of late, she has been more or less persistently nauseated. Nausea has no relation to meals or types of foods. It lasts for about two hours and then disappears. She stated that she had had jaundice at five years of age. Her past history was essentially negative other than the jaundice, as was her family history.

Physical examination revealed that she was quite tender over the gall-bladder, less so over the appendiceal region. Exhaustive studies of her gastrointestinal tract revealed no pathology to account for her symptoms, and in spite of management these attacks continued to recur. She developed some dizziness. This vertigo became a prominent symptom in her clinical picture. Exhaustive ophthalmological, otological and neurological examinations by very competent consultants failed to enlighten us as to the possible source of her symptoms and complaints. And yet, in spite of it all symptoms persisted. With all these findings essentially negative there still must be some source for these manifestations, and she was therefore told to see a psycho-analyst who found a very definite incompatibility at home, associated with a fear of pregnancy. Following management in the hands of the psycho-analyst her symptoms have entirely disappeared. The patient is exceedingly happy and is very comfortable.

A similar case to this is a patient who has had a diarrhea for years and years and years, ever since she has been married. The most exhaustive search for the cause of the diarrhea from a gastro-intestinal standpoint revealed nothing. There were no allergic manifestations to serve as etiologic factors. Feeling that there must be some reason for these gastro-intestinal upsets, she was also referred to a psycho-analyst. He found that there was incompatibility in the home and some brutality on the part of the husband in presumably intelligent surroundings. Since these have been corrected, she is entirely free from her gastro-intestinal symptoms. This further emphasizes how frequently large bowel disturbances may be on the so-called "functional basis." This observation has been made so repeatedly that even the laity are acquainted with the influence of nervous disturbances on the so-called "stomach and bowel."

I have repeatedly called to your attention the numerous cases of cardiac involvement which come in complaining mainly of gastro-intestinal symptoms. When one realizes the marked hyperemia of the liver and the hyperemia of the gastro-intestinal tract, is it any wonder that these patients complain so frequently of abdominal symptoms? These manifestations

may become so acute that to all intents and purposes they simulate an acute surgical abdomen, particularly resembling that of acute gallbladder. And to carry the clinical picture a little further, these patients may frequently develop jaundice and it has been explained by some that this bilirubinemia is associated with infarction in the lung, and the increased amount of serum bilirubin liberated is just enough to be retained in the blood stream due to the rise of the liver threshold for the secretion of bilirubin. So one should be careful in coming to too rapid a conclusion regarding a surgical abdomen in the presence of a decompensated heart. Coincident with the improvement of the cardiac manifestations, so do the gastrointestinal symptoms subside. Similarly, one sees gastro-intestinal manifestations in disturbances of the kidney.

Low grade nephritides or chronic uremia may have no symptoms at all pointing to the urinary tract. The entire clinical picture may resemble that of a disturbance in the abdomen. I do not emphasize at this time those acute manifestations of kidney pathology which resemble acute manifestations in the abdomen, but I am sure they have been sufficiently emphasized to you in your other courses. Here again under therapeutic management in those cases which respond to our best known methods of therapy at the present time in our attack on renal disease, the abdominal picture completely subsides. These manifestations do not resemble any particular disease of any one organ and it is for that reason they offer some difficulty in diagnosis from the abdominal viewpoint. How often does one see in women complaints which they think are entirely digestive in origin that may be associated with pathology in or about the pelvic organs. Just recently there was called to my attention a young woman who had been repeatedly treated for various diseases of the gastro-intestinal tract which on very careful search I found nothing which would account for her gastro-intestinal symptoms. But I did find a very large, incarcerated ovarian cyst which, when removed, entirely cleared up clinical manifesta-

tions. Tubal and uterine pathology are equally responsible for upper abdominal manifestations.

Now, while I admit that maybe I have left out some systemic manifestations which cause abdominal disturbance, I have tried to bring home to you this morning the one important outstanding clinical fact, that the clinician should never be gullible; the fact that a patient complains of his or her stomach is no reason at all for you not to read between the lines and find out if there is remotely some other cause for those symptoms. When examining a patient for gastro-intestinal symptoms, you begin at the head and go right down to the feet as you would in any other type of examination and then begin to correlate your abdominal findings with findings elsewhere. Then you can make an exhaustive study from the laboratory and x-ray standpoints to see if there is enough pathology in the gastro-intestinal tract to account for the symptoms. Finding that pathology lacking, it may be necessary for you to search further as to the possible cause of the disturbance. It is only by this type of clinical practice you are able to arrive at a more accurate conclusion and a more accurate diagnosis in any one given case.

MICHAEL REESE HOSPITAL

TREATMENT OF COMA

SINCE coma is a symptom of many underlying conditions it is axiomatic to say that the treatment of coma must depend on the nature of the etiologic factors involved. Therefore it would be unwise to discuss treatment without at least a cursory analysis of the causes. In the diagnostic studies made on any given case of coma we frequently find that the diagnostic procedure also becomes good therapy. It will be seen in the course of our subsequent analysis that not infrequently the diagnosis and therapy are virtually the same.

Even assuming the necessity for an etiologic diagnosis in a case of coma, it must be faced at the outset that not all cases lend themselves to proper diagnosis. Sometimes the wise physician must stand aside for the march of time to clear the picture. During this period, however, the same diagnostic procedures should be adopted as would apply to any other kind of a case. Despite the fact that the patient is in coma, all available history obtainable from family or friends should be accumulated. At times this may mean considerable effort on the part of the physician, but the results usually are worth the effort. Emphasis should be placed on this point because the natural tendency in a case of coma is to act. As an illustration of the value of obtaining a history, one may cite the case of a woman picked up in a department store and brought into a hospital apparently with hemiplegia. Without any clue obtainable from her it was impossible to make a diagnosis until the family arrived and informed the physician

that she was a patient of one of us (S. S.) and taking insulin. When we were called in the next day we found that instead of taking 8 units of insulin she had taken 80.

The alcohol breath which may be found in so many cases of coma is in itself of little value, but if an attendant makes the statement that the patient never drank or the opposite statement, that the patient is a confirmed drunkard, much diagnostic and therapeutic help is obtained.

Again, before attempting any therapy a most careful physical examination is indicated, and even at the risk of emphasizing the obvious, we believe it necessary to stress the extreme value of accurate observation, particularly of the skin, mucous membrane, and the type of breathing. The diagnosis may be made in certain cases of coma by the presence or absence of cyanosis, Cheyne-Stokes breathing, the Kussmaul breathing or a slow or shallow breathing. Signs of external injury demonstrable by blood coming from the nose, mouth, eyes or ears, injury to the scalp, and the signs of trauma anywhere else in the body must be carefully looked for. The odor of the breath, of which we have previously spoken, may or may not be of importance but must be carefully noted. It is not always possible particularly in the presence of mouth infection to distinguish types of odor in the breath.

A study of the reflexes and of muscle tone and all the other tests which go to make a good neurologic examination are of course indicated. Whatever is found from this examination must be carefully analyzed. The absence of reflexes, for instance, may be the result of shock rather than a sign of prime importance. Pin-point pupils of opium poisoning as contrasted to the dilated pupils associated with barbitol poisoning may form a decisive point in differential diagnosis. The finding of an enlarged heart and fibrillating pulse in the case of coma suggests naturally a cerebral embolus, and a fast feeble pulse may indicate the failing heart of hemorrhage, coronary disease, or may be a terminal finding.

In the treatment of a case of coma the presence of sugar, acetone or albumin is of obvious significance, but it should be

emphasized that no one of these substances is absolutely specific. Sugar may occur not only in diabetes, but in almost any type of brain injury. Acetone while it may indicate diabetic acidosis, especially when associated with other clinical signs, may occur in starvation and be of absolutely no diagnostic value. Albuminuria likewise cannot be interpreted entirely in association with other physical findings. The urine in all cases of coma should be saved so that if there is other evidence to suggest poison, the specific poison may be looked for.

Interpretation of the blood pressure will depend to a great extent on any information obtainable concerning the preceding state of the blood pressure. If a patient is seen with peripheral arteriosclerosis and a low pressure and we are told by the family that he previously had a high blood pressure, we immediately must suspect a cerebral accident.

No better illustration of the point mentioned earlier regarding the relationship between diagnosis and therapy can be cited than gastric lavage. Perhaps done primarily for diagnostic purposes, the diagnostic test immediately becomes a therapeutic procedure.

It is our belief that lumbar puncture may be used as a routine procedure, either diagnostically or therapeutically, and may clear up the whole picture.

From a therapeutic point of view coma cases may be divided into four groups: (1) Those requiring immediate trephining, (2) those requiring stomach lavage and antidotes for drugs or other poisons, (3) those requiring specific treatment as in diabetic coma or a real case of poisoning, and (4) those requiring rest and watchful waiting.

Fortunately only a few cases require immediate trephining and they are the ones which show evidence of increased intracranial pressure, such as increase in blood pressure, with slow pulse, nausea and vomiting, and choked disk. Such cases usually are either traumatic or may be due to brain tumor, and usually a trephining operation is then performed. If the increased pressure is due to cerebral hemorrhage and if this

hemorrhage arises from the middle meningeal artery, this artery may be ligated.

The first treatment of cases due to poisoning is lavage of the stomach. If the specific drug can be found antidotes should immediately be given. In cases of morphine and barbitol poisoning, potassium permanganate is used in the lavage solution. If mercury is the etiologic factor milk or egg-white should be used.

Coal gas poisoning is usually identified by the cherry red color of the patient and specific changes in the spectroscopic bands. Treatment by oxygen and carbon dioxide inhalations is urgent, and according to some, intravenous injections of methylene blue may be helpful.

In not all cases can a specific drug be identified and certain general measures are indicated. A strong cathartic, such as Epsom salts or castor oil, should be given after the lavage. Stimulants, such as caffeine, strychnine and coramine, may be of urgent need. Intravenous glucose is a rapid method of stimulating urinary secretion. This may be used in 5 to 10 per cent solution or even stronger. In all cases the patient should be kept warm by blankets, hot-water bags or electric pad, and should be turned frequently from side to side. Artificial respiration may be compulsory in some cases. The feeding problem is not easy but an effort should be made to maintain nourishment. Rectal feeding is not very satisfactory but has to be used. A nasal catheter may have to be used, especially in cases of poisoning from caustic drugs. The nasal catheter is generally speaking the best means at our command at present.

In the third group of cases, namely, those with a specific etiology, we find our most satisfactory results in diabetic coma. In this condition it is necessary constantly to keep in mind the principle for which one is striving. For instance, the height of the blood sugar or even the exact amount found in the urine is not important because the coma depends on acetone bodies rather than on glycosuria. In the treatment of diabetic coma insulin is a specific and provided there are no

complications will in the majority of cases result in restoring the patient to consciousness. Although insulin can never be given blindly, it is always safe to give a comparatively large dose in a proved case of diabetic coma, and in general practice where the controls may not be as accurate as they would be in an institution, we believe it is safer to combine insulin with glucose in some form. To be more specific, the initial dose may be anywhere from 30 to 50 or 60 units without bothering about extra glucose. More than 60 units at a single dose is of little value. The patient's clinical condition is watched and the urine studied, particularly from the standpoint of sugar and acetone. The further treatment is determined by the course of events. The urine should be examined every two hours, even if it is necessary to catheterize the patient. If at the end of the first two hours there are signs of diminishing acidosis the amount of insulin may be reduced to 20 to 40 units, but at this time we believe it is wise to add glucose either in the form of hypodermoclysis (2.5 per cent solution) or by mouth if the patient is now able to drink orange juice or milk. As the acidosis clears up the insulin is further reduced. If despite large initial doses there are no signs of improvement more insulin should be used, but this should be controlled not only by urinalysis but by blood sugar studies. The careless use of insulin must be distinguished from the use of large doses, because the careless use of too large doses may result in hypoglycemia and coma due to this condition. We have seen this happen and we believe that it is a fairly common occurrence which must be guarded against.

General measures are of extreme importance in diabetic coma. The patient must be kept warm, the bowels should be emptied by a cleansing enema, and particularly, dehydration, which is so commonly a concomitant symptom, must be combated. Hypodermoclysis should be instituted immediately and should be continued until the dehydration is controlled. The heart bears a terrific burden and must constantly be watched, particularly in older people. When the treatment of the dehydration does not improve the cardiac condition,

most drastic treatment is indicated. During and immediately after the coma no great attention need be paid to the control of the diet, since carbohydrates are definitely indicated during this period. However, as soon as the patient passes the borderline, the usual principles of dietetic therapy are applicable.

In contrast to the dramatic specific therapy of diabetic coma, the case of uremic poisoning offers only certain general therapeutic principles. Perhaps the intravenous injection of glucose solution, 200 to 300 cc. of a 10 to 25 per cent solution at intervals of a few hours, offers the best therapeutic hope. Small but repeated transfusions preceded perhaps by venesection have given good results in some hands. The use of stimulating drugs, such as digitalis or caffeine, are certainly indicated when the heart or peripheral circulation fails. Some investigators have claimed rather brilliant results from the use of intravenous solution of 40 per cent urea given in 50 cc. doses every eight hours. We have not seen as good results from this procedure as have been reported in the literature.

In the fourth group belong practically all cases of coma due to accidents to the cerebral blood vessels. Much has been written about the diagnosis and treatment of these conditions. Our own experience suggests that at times it is almost impossible to differentiate cerebral hemorrhage from thrombosis and a careful analysis of our results suggests that the less interfering therapy is used the better the prognosis. At the onset it is impossible to predict the outcome. What looks like a mild cerebral accident may progress steadily downhill, and what starts off as a wild outburst may quiet down. It has been our policy not to do a venesection, lumbar puncture, or move the patient. We believe that the patient should be kept where he is whenever possible, at least for the first twenty-four hours, and nothing whatever but careful watching and nursing is indicated. In the presence of extreme restlessness or convulsive seizures morphine or opium derivative is indicated to obtain the essential quiet and rest. After the first twenty-four hours the general condition of the patient requires

attention. Dehydration is to be avoided. The bowels must receive attention and, if necessary, stimulation by caffeine or digitalis given.

Not all possible causes of coma have been included in this discussion nor has anything been said about the problems involved when the patient has one disease and gets coma from something else. The diabetic may go on an alcohol spree and when he is seen by the doctor it is not an easy matter to decide whether he is suffering from alcoholism or from diabetic coma. The patient with a known duodenal ulcer may take an overdose of a drug and it will require keen diagnostic judgment to decide whether the coma is due to cerebral anemia from hemorrhage or to a drug. The type of case which will be most common in one locality or one institution may be less common in another. Alcoholism, for instance, is very rare at Michael Reese Hospital, while in the public institutions it is apt to be one of the commonest causes of coma.

CLINIC OF DR. WILLIAM A. BRAMS

MICHAEL REESE HOSPITAL

VENOUS PRESSURE

EVERY clinician is familiar with the close relationship which exists between arterial blood pressure and myocardial function of the left side of the heart. It is not so generally recognized that venous pressure is a very reliable index of functional capacity of the right side of the heart with the result that estimation of pressure in the peripheral veins has not as yet become a popular procedure in clinical medicine. It cannot be said that determination of venous pressure is a recent development, for Stephen Hales in 1733 reported his experiments in these words: "In December I laid a common Field Gate on the Ground, with some Straw upon it, on which a white Mare was cast on her right side, and in that Posture bound fast to the gate; she was fourteen Hands and three inches high; lean, tho' not to a great Degree, and about ten or twelve Years old. . . . Then laying open the left Jugular Vein, I fixed to that part of it which comes from the Head, a Glass Tube, which was four Feet, and two Inches long. The Blood rose in it, in three or four Seconds of Time, about a Foot, and then was stationary for two or three Seconds; etc., etc."

Nor can it be said that modern clinical methods for estimating venous pressure are difficult or inexact. Practically all procedures may be classified as either indirect or direct. Most of the indirect methods are based on the principle of compressing a visible, superficial vein in the skin by means of a transparent air chamber and reading off on a water manometer the pressure necessary to obliterate completely the vein under examination. These methods are used widely and are easy to perform but considerable experience is needed to recog-

nize the end point of compression, a change which is not always sharply defined.

We prefer a direct method because it is more accurate and the end point is always distinct. A simple instrument designed by Dr. J. S. Golden and myself overcomes the usual objections raised against direct methods, namely, that the hollow needle may become plugged by a clot and that prolonged observations are impractical. Our apparatus consists of a small metal reservoir and a water manometer, both being connected to a small hollow needle by a glass T tube and suitable rubber tubing. The entire instrument is carried in a small metal box, in which it may be autoclaved and both the reservoir and manometer may be easily attached to the opened cover when readings are to be made. Sterile 3 per cent sodium citrate solution is poured into the reservoir and manometer and the fluid is allowed to fill the tubing and needle, care being taken to expel all air bubbles. The patient is kept in a recumbent or semirecumbent position with the arm well abducted for at least fifteen minutes and the level of the auricle is marked on the side of the thorax according to the suggestion of Eyster. The hollow needle is then introduced into the cubital vein and citrate solution from the manometer tube is permitted to flow into the vein until the level of the solution in the manometer tube becomes stabilized. The height of this level above that of the auricle represents the peripheral venous pressure. The apparatus may be maintained in faultless working order for three to four hours without discomfort to the patient and without removal of the needle from the vein by permitting a few drops of citrate solution from the reservoir to flow through the needle into the vein every five minutes.

We have adopted a range of 5 to 10 cc. of citrate solution above the level of the auricle as the normal venous pressure when taken according to our method. Abnormal variations are found in many conditions, but we shall briefly describe our clinical experience with venous pressure in cardiac failure and with certain therapeutic measures used in combating this condition.

It must be stated at the outset that an abnormal level of venous pressure is not a sign of any particular valvular defect or special anatomical lesion. It does furnish very important information as to the myocardial capacity of the right side of the heart. Any condition which leads to failure of the right side of the heart causes a rise in peripheral venous pressure but so-called "pure, left sided failure" causes no such change. Hence, the procedure is of value in distinguishing these two forms of failure in which the treatment is also different. It is of further advantage to estimate venous pressure in instances of right sided failure because cyanosis and the apparent size of the cervical veins may at times be misleading. For instance, much more carbon dioxide in the blood and oxygen deficiency will be necessary in cases of anemia to produce a given degree of cyanosis than in normal persons and much less in patients with an excessive number of red blood cells. This is merely an example of the extracardiac factors which may have an important relation to the degree of cyanosis. We have observed that the apparent degree of engorgement of the cervical veins may be deceptive. Large cervical veins may be due chiefly to emaciation or to local obstruction. Measurement of venous pressure in such instances will furnish much more reliable information than mere inspection.

Elevation of venous pressure in a patient known to have cardiac disease but who is apparently in a good state of compensation will sometimes serve as a warning of impending failure. It may, in fact, be the earliest sign of impending cardiac defeat in a patient in whom such a state is not suspected. The information gained by repeatedly estimating venous pressure may be of value in following the progress of right sided failure. Tendency of venous pressure to fall usually means improvement while persistence of a high level or tendency to rise frequently presages complete cardiac defeat. The results of treatment may also be followed by such repeated observations and great value is placed by some on estimation of venous pressure as a guide for the performance of venesection in instances where venous pressure is high. Dr.

J. S. Golden and I were interested in the value of so-called "bloodless venesection" in patients with heart failure and high venous pressure. As is well known, the procedure consists of constricting all four limbs near the trunk; sufficient compression being applied to permit inflow of blood into the limb while outflow via the veins is prevented. It was thus hoped to relieve the heart of a certain quantity of blood by imprisoning blood in the limbs and to accomplish this without actual loss of blood, since hemorrhage is not always well borne by patients with heart disease. We permitted the constrictors to remain in position for thirty minutes after control readings were taken and measured venous pressure in one unobstructed limb at intervals of five minutes. Blood pressure was also measured and the pulse rate counted at the same intervals. We could find no change in venous or arterial pressure or pulse rate, although the same patients showed an immediate and partially sustained drop in venous pressure after ordinary blood letting. We have, consequently, omitted this procedure from our therapeutic armamentarium.

Dr. Golden and I performed a series of experiments to determine the effect of ordinary blood letting on patients with varying degrees of cardiac failure with and without elevated venous pressure. We found no change in the pulse rate and only a transient fall in arterial blood pressure, but venous pressure fell in every instance. The fall in venous pressure was marked in many instances but nearly always returned about halfway toward the previous level within an hour. We have watched the ultimate course of these patients and believe that venesection may be of benefit in some cases of right sided failure with high venous pressure, but we cannot share in the enthusiasm of ardent advocates of venesection. We have followed many patients after venesection and are convinced that more conservative measures would have been of nearly equal benefit. It is possible that our patients had very little cardiac reserve, but we are inclined to rely on digitalis, sedatives and diuretics and to advise venesection only occasionally in right sided cardiac failure.

CLINIC OF DR. HEYWORTH N. SANFORD

PRESBYTERIAN HOSPITAL

THE IMMUNIZATION OF INFANTS AND YOUNG CHILDREN AGAINST INFECTIOUS DISEASES

ONE of the most important fields of pediatric procedure exists in the immunization of infants and children against infectious diseases. This has been so popularized among the general public that at the present time most parents are more than anxious to cooperate with the physician on these measures. It is well, however, to realize that not all infectious diseases can be prevented by definite control measures. Unless this is made clear to anxious parents, extravagant promises of disease prevention will cause doubts to arise in the public's mind that will destroy all confidence in preventive pediatrics. It is well, therefore, to divide these diseases into two groups. First, those in which we have a definite method of prevention and immunization, and second, those in which we have a partial or limited method of control.

THOSE COMMUNICABLE DISEASES FOR WHICH THERE IS A DEFINITE METHOD OF PREVENTION AND IMMUNIZATION

Smallpox.—During epidemics of smallpox, vaccination should be performed at any age. This includes infants in the newborn period. As a general public health procedure, infants should be vaccinated from the sixth to the twelfth month of life, or not later than the eighteenth month of life. The reasons for doing so at this time are that they are given protection from the disease (there is hardly any inherited immunity), the reactions are almost negligible at this age, and lastly, post-vaccinal encephalitis hardly ever occurs under eighteen months of age.

In the absence of an epidemic, it is usually well to postpone vaccinating children afflicted with such skin diseases as eczema, impetigo, and furunculosis. Infants suffering from severe gastro-intestinal upsets, or marked malnutrition may be spared the added burden of vaccination until they are stronger. While it is probably quite hypothetical, I believe that the best time for vaccination is in the late spring, early summer and fall. Obviously the hot months are depressing and excessive perspiration may cause scratching of the pustule and secondary infection. During the winter and early spring the child may suffer from a respiratory infection or contagious disease. While most parents are intelligent enough to know that these diseases are not caused by the vaccination, still in the back of their minds they will wonder if the vaccination did not lower the child's resistance to the disease.

Vaccination may be done on any skin surface. The preferred site in boys is at the point over the insertion of the deltoid muscle on the left arm. In girls, the outer aspects of the left thigh, at a point two thirds of the way from the knee to the hip is the best location. One is accustomed to looking for a scar in these locations in examinations, and there is no reason for placing the vaccination in bizarre localities.

The site of vaccination should be thoroughly washed with acetone. Other antiseptics may destroy the virus. A drop of virus is placed in the center of the cleansed area. Holding a small sterile needle at an angle of 20 degrees from the skin surface, the point of the needle is pressed into the skin through the drop about ten times. Obviously these pressure points should be in the same locality. No blood or serum should be drawn. The excess of virus is now wiped off with a piece of sterile gauze.

There is some difference of opinion as to the advisability of putting a dressing over the inoculation. It is permissible to use no dressing. Certainly tight constricting bandages and shields should be strictly avoided. I always put one thickness of sterile gauze over the point of inoculation very loosely with a piece of tape. The mother is told to remove this next morn-

ing and put nothing more on it until the pustule appears. She is then told to place a similar piece of gauze on the pustule, and to change it daily unless the pustule breaks and sticks to the gauze. If this happens the gauze is not removed. No tub bath is given the child from the time the pustule appears until the scab is on firmly. The mother is warned that a papule usually appears on the third to fifth day. In another day this becomes a vesicle and the next day a pustule with a swollen red area around it. At about the sixth day there is frequently some fever and loss of appetite. Mothers are told to report one week after vaccination for inspection and further instructions.

Reactions will fall into three groups. Successful primary vaccinations in which a pustule is present on the seventh day; an unsuccessful vaccination shows no reaction to the virus and confers no protection against smallpox. Those who fail to react after a primary vaccination with the production of a pustule should be revaccinated after two weeks. Children revaccinated after a previously successful result may show a reddened, inflamed macular or maculopapular area at the vaccination site at about forty-eight hours. This is evidence of persistent immunity from the previous vaccination.

The complications of vaccination are secondary infection, generalized vaccina, autovaccination and postvaccinal encephalitis. If the procedure is carried out as outlined, secondary infections are very uncommon. They were more common when shields and tight bandages were used. They can be told by excessive swelling, abscess formations and lymphatic enlargement. Secondary infection of the pustule may be treated by cleansing the pustule with ether and painting with a mild antiseptic as gentian violet or mercurochrome. Abscesses should be treated surgically with wet dressings.

Generalized vaccina occasionally happens. It varies from scattered pustules around the primary lesion to scattered papules and vesicles over the entire body. The child may have several degrees of temperature and be quite prostrated. There is nothing to do for these children except to give anti-

pyretics for the temperature. The prognosis is excellent and recovery rapid. Those children who have eczema or delicate skins appear more likely to have such reactions.

Autovaccination is caused by not wiping off the excess of vaccine which the child scratches and carries to other parts of the body, or by scratching an uncovered pustule. The most common points are the lips, cheeks or eyelids. They follow the course of the original vaccination. Nothing can be done and they are unimportant with the exception of the eyelid or cornea. This is very serious and may cause loss of the eye. Call an ophthalmologist into consultation immediately if this happens.

Postvaccinal encephalitis has received considerable attention abroad. In this country only 75 cases have been reported. Considering the number of antismallpox vaccinations performed yearly, this number is very small. In the countries where postvaccinal encephalitis occurred, it affected children mostly of school age; only rarely has a case occurred in infants under two years. An exception is Germany, where nearly all cases are between one and two years. However, most children in Germany are vaccinated at that time.

The symptoms appear suddenly, on the tenth to the thirteenth day following vaccination. Fever of 104° F., vomiting, headache, stupor and positive Babinsky are the most important symptoms. The course is stormy and the prognosis is grave. The mortality is 40 per cent. Recovery, when it takes place, is usually rapid and complete. Besides the usual treatment for encephalitis, the child should be given blood serum from a recently vaccinated person.

As a preventive measure for vaccine encephalitis, the following principles should be used in vaccination. Primary vaccination should be done early in life, during the first year if possible. No person should be vaccinated unless in perfect health. Mass vaccinations are to be avoided. In Holland, most cases of postvaccinal encephalitis occurred in March and April. Multiple scarification and cross hatching were condemned by the English committee. Armstrong recom-

mends that primary vaccinations, especially after the first year of life, be deferred until immunization against diphtheria or other diseases has been accomplished, as this preliminary exercise of the immunity or defense forces may lead to a more efficient antiviral response.

Diphtheria.—Immunization against diphtheria should be a routine procedure. Most infants have a natural immunity to diphtheria at birth that begins to fall off at about the sixth month. For this reason it has been advocated that immunization should be begun at this time. Certainly in infants living in slum surroundings, more liable to infectious contacts, this is advisable. In the average infant that has medical supervision, I do not think it is advisable to immunize before one year of age, but it should be routine at this time. Certainly in babies of this type, diphtheria under eighteen months of age is quite uncommon. Furthermore, the work of Greengard indicates that the passive immunity in young infants interferes with the development of antitoxin in response to vaccination with diphtheria toxoid. The only infant in my experience that died of diphtheria under fifteen months of age had received toxoid at six months of life.

Immunization should be routine at one year and advocated up to ten years. A Schick test preliminary to immunization is unnecessary for children less than seven years of age. For older children it is desirable to determine the need for immunization.

Toxoid should be employed for children under seven years of age. At the present time most men are using two doses of 1 cc. each, at not less than two- nor more than four-week intervals. Some give three doses which probably gives a higher immunity, but inasmuch as two doses of 1 cc. each at two- to four-week intervals give a 90 to 95 per cent immunity, this hardly seems necessary. The one dose alum precipitated toxoid in amounts of 0.5 to 1 cc. (varying with different preparations) may supplant the other toxoid. It has the advantage of one injection because of slow absorption. It appears to be very successful in children under seven years

of age. It should be used with great care in older children because of local reactions.

The arm over the deltoid region is cleansed with soap, water and alcohol. The toxoid is given in a sterile syringe and needle subcutaneously. Be sure that there are no air bubbles in the syringe, and that the needle is wiped dry, also do not use formaldehyde toxoid solution unless it is perfectly clear. The injection site is covered with a sterile gauze bandage, removed the next morning. The mother can be assured that there will be no reaction at this age. The second injection is given in the other arm in two to four weeks.

Immunization with toxoid should never be done for a child of over seven years without first testing their reaction to it. This is done by injecting 0.1 cc. of toxoid intradermally. If within three days an area of redness measuring more than 10 mm. develops, either one of two procedures may be used. The first is to use toxoid, giving one dose of 0.2 cc. subcutaneously followed in two weeks by a second dose of 0.5 cc. and in two more weeks by a third dose of 1 cc. In the event of a reaction after the first dose, the amounts subsequently injected should be cautiously increased or the same dosage repeated. Immunity may be produced by three injections of as little as 0.2 cc. each. The second method is to use toxin-antitoxin mixture, which generally produces less reaction in older individuals. Three successive injections of toxin-antitoxin mixture, in amounts of 1 cc. each, can be given subcutaneously, from one to two weeks apart.

Diphtheria immunization is worthless unless it is followed up with the Schick test. While with the two-dose method of toxoid, 90 to 95 per cent of children will become immune within three months, the five or ten children who are not immune could spoil the effect of the entire procedure by raising doubts in the mother's mind as to the reliability of the method.

Diphtheria toxin for the Schick test is supplied in ten test ampules. The ampules are 1 cc. each and contain diluted toxin in peptone solution. They are stable for a period of months, as stamped on the bottle, if precautions are used.

These consist in keeping the bottle in the ice-box when not in use, and thoroughly wiping off the rubber top with alcohol before piercing with the needle. Obviously the needle and syringe should be sterile. Use a syringe graduated in 0.1 cc. and a fine needle (26 gauge) with a rounded point. Cleanse the flexor surface of the arm with soap and water and alcohol and inject 0.1 cc. of the diluted toxoid intradermally. A superficial bleb should result, through which the hair follicles can be seen. Cover this with a piece of sterile gauze, to be removed the next morning.

The test is read in forty-eight to seventy-two hours. A positive reaction is shown by redness of the skin covering an area of over 10 mm. in diameter. Positive reactions usually stay red for several days, turn brown and scale over the point of injection. A negative reaction shows a red area less than 10 mm. Schick tests have been made on so many children with such conformity of results, that the mother can be assured that her child is now immune to diphtheria. As a further safeguard, it should be recommended that the child be re-Schicked on entering school, or in the presence of an epidemic. Some children have been known to lose their immunity in four or five years. If a positive reaction is obtained, one may wait another three months and repeat the Schick test, or give another 1 cc. of toxoid at once, and re-Schick at three months. Some children will no doubt become negative in another three months, but I always give one more dose of toxoid to be safe. Schick reactions are uniformly negative after the third dose of toxoid.

It must be emphasized that immunization does not take place for three months and none of these methods should be relied upon for active immunity in the presence of diphtheria. In such cases 1000 units of diphtheria antitoxin should be given intramuscularly. Remember that this is a horse serum and the child may be sensitive to it. All children with a history of eczema, asthma, or any sensitivity, or who have had any horse serum before (including toxin-antitoxin mixtures) should be tested for sensitivity before giving the injection, by injecting intracutaneously 0.1 cc. of a $\frac{1}{10}$ or $\frac{1}{100}$ dilution

of antitoxin. If no wheal or marked zone of erythema appears within thirty minutes, the full dose may be given. If such a reaction appears, the antitoxin should be given in divided amounts beginning with 1 cc. in $\frac{1}{100}$ dilution with saline solution. At intervals of thirty minutes increasing amounts may be given until the entire amount is completed. This should be given in an extremity, so that rapid absorption can be impeded by a tourniquet if an immediate reaction issues. In case of a severe reaction, 3 to 6 minims of a $\frac{1}{1000}$ epinephrine solution should be given subcutaneously.

Typhoid Fever.—While immunization against typhoid fever is a definite prophylactic procedure, it is not necessary in most communities for universal application. Its use should be restricted to those communities where typhoid incidence is great and particularly if a trip is planned to such a region. This applies particularly to Europe and the Orient, or to rural communities in this country where the water supply is questionable.

Immunization could probably be given to the child at any age. Certainly at one year of life it would be satisfactory. The vaccine given for adults is in amounts of 0.5 cc. for the first dose and 1 cc. for the second and third doses. There is no definite amount recommended for children. I usually give children over eight a full adult dose and under eight years two thirds of the adult dose. The injections are given subcutaneously in the deltoid region at one-week intervals. As a rule, children have no reactions. It probably takes about three months to establish an immunity. There is no simple laboratory test for determining typhoid immunity, but it is assumed that immunity lasts at least two years. If protection is to be assured beyond this time, a second course of injections should be given, or one dose may be given each year following the original course of three.

Tetanus.—Tetanus antitoxin should be always used prophylactically in all cases in which a wound is contaminated with horse manure or human excreta. This, therefore, includes all wounds of the street, in gardens, or any spot where

street dirt may have been trampled. Also all wounds contaminated with water at bathing beaches, or industrial injuries. It is particularly indicated in puncture wounds or wounds about the head. The prophylactic dose is 1500 units injected subcutaneously. Remember that this is a horse serum and the precaution mentioned under diphtheria should be followed.

At the present time there is much work being done on vaccination against tetanus, which may develop into a standard procedure later. Ramon has been using an anatoxin mixture in French soldiers with apparent success. Bergey and Etries in this country recommend one injection of a 1 cc. alum precipitated tetanus toxoid for immunization. This is given in one injection and gives an immunity in three to six months. They claim there are no reactions. At present, however, only antitoxin should be relied on.

THOSE DISEASES IN WHICH PREVENTATIVE MEASURES ARE LIMITED OR INDEFINITE

In these diseases the mother should be told that the methods of immunization are not perfect. It is folly and detrimental to the public faith in preventive pediatrics to make extravagant claims as to immunizing children for these conditions.

Scarlet Fever.—Natural immunity is found in many children, and a considerable number of adults. Inherited immunity is present in the newborn if the mother is immune, and lasts in one half the children for six months and in one third for twelve months. Clinically scarlet fever is uncommon under two years. For this reason infants may be Dick tested at any time, preferably after one year. I test routinely between eighteen months and two years.

Dick test material is obtainable in 10-test ampules and 100-test ampules. The 10-test ampules are glass topped and must be used at once. The 100-test ampules have a rubber top and if care is used as outlined with Schick test material (use acetone to sterilize top, not alcohol), they may be used until the expiration period stamped on the bottle. Great care

must be used in performing the Dick test. Use a syringe graduated in 0.1 cc. and a 26-gauge needle with a round end. Boil the syringe and needle in distilled water. Use no alcohol. Cleanse the skin with acetone. Expel at least 0.1 cc. of the scarlet fever toxin from the needle before using. Inject accurately 0.1 cc. of the scarlet fever toxin intradermally. Injections must be intradermal as a subcutaneous injection may show negative results in a positive subject. Cover with a sterile gauze bandage and read in twenty to twenty-four hours (not later). Unlike the Schick test there will always be some erythema. If the area of redness measures over 10 mm. in diameter, the test is positive.

If the test is negative, it may be assumed that the child is immune to scarlet fever. However, it must be remembered that this test is not perfectly reliable. Persons with negative Dick tests have been known to contract scarlet fever. The mother should be warned of this and told to have the child retested in the presence of a scarlet fever contact, or epidemic or in any case in two or three years.

If the test is positive, all of the factors that enter into the situation should be explained to the mother. Nursing groups, personnel of contagious hospitals and orphanages, or groups intimately exposed to scarlet fever should be protected. The Committee on Prophylactic Procedures Against Communicable Diseases of the American Academy of Pediatrics does not recommend active immunization by scarlet fever streptococcic toxin as a general public health procedure because local and general reactions are frequent in adults and not altogether absent in children. Also the degree and duration of the immunity have not been definitely established. However, the degree of reaction is certainly not as bad as a case of scarlet fever. I believe that the principal argument against it is the degree and duration of immunity. These facts should all be laid before the mother and let her decide. I certainly would not force the immunization against her desire not to have it.

Active immunization, if decided upon, consists in the injection of five increasing doses of scarlet fever streptococcus

toxin at weekly intervals. These injections are made subcutaneously as with the diphtheria toxoid. This material is put up in 1-cc. vials and are numbered one to five. Great care must be taken to give these doses in order as they increase rapidly in toxin and would cause serious reactions if given out of order.

It is stated that about 10 per cent of susceptibles will show general reactions after the first dose and about the same number following the last dose. From my own experience, I would say that 30 per cent was a closer figure. These reactions are a temperature up to 102° F., vomiting, diarrhea, and headache. These come on in a few hours and last about twenty-four hours. They may be treated symptomatically. I find the vomiting most troublesome. It may be necessary to withhold all food and give only tablespoonfuls of water for twenty-four hours to control it. In the presence of severe reactions it is best to divide the next dose of toxin, and give it the following week. If there are no reactions, the usual routine can then be followed.

Two weeks after the last dose of toxin, repeat the Dick test with 0.1 cc. of toxin in the right arm and 0.2 cc. in the left arm. If either test is positive, repeat the fifth dose, after which 95 per cent of the susceptibles will become negative. The mother should be instructed to have the Dick test repeated again in one or two years, or in the presence of a contact or epidemic.

This active immunization, of course, takes at least five weeks and is valueless for a susceptible contact. For these children, convalescent scarlet fever serum has been recommended for passive protection. It is given intramuscularly in amounts of 10 to 20 cc. The evidence as to its reliability is inadequate, but it should cause no reactions and I think should be used if obtainable. Scarlet fever antitoxin is also used for passive immunization. Its use is frequently accompanied by unpleasant horse serum reactions and the evidence regarding its value is indefinite.

Measles.—There is no method for active protection

against measles. The disease may be prevented, or better, modified by the injection of blood serum of a person recently convalescent from the disease, or the blood serum of adults.

Human blood serum taken one to three weeks after the fever of measles has subsided should be used. When administered within five days after exposure in doses of 10 cc. intramuscularly it may protect against the disease. It usually lessens the severity of the disease in any case and should be used in children under three years of age, or those suffering from another disease, particularly a respiratory infection. Under ordinary circumstances, it is more desirable to produce modified measles than to protect completely. Ten cc. of convalescent serum given six to seven days after the child has been exposed produces partial protection. That is, measles develops in a mild form.

Thirty cc. of normal adult whole blood, or 20 cc. of normal adult serum, will produce somewhat the same effect as 10 cc. of convalescent serum. It probably is not as reliable due to differences in protective substances. Measles modified by convalescent serum or normal blood apparently produces a permanent immunity comparable to the disease. McKahn has advocated the use of placental extract. It is believed that 2 cc. injected on the sixth or seventh day after exposure will usually modify the disease. This method could be used in the absence of convalescent serum, or adult serum.

Whooping Cough.—A vaccine for the active immunization against whooping cough has been developed by Sauer. This vaccine differs from the older types in that it is prepared from fresh strongly hemolytic strains of *B. pertussis*, grown on medium made with freshly defibrinated human blood. This gives the advantage of more massive doses than with the older vaccines. It apparently gives considerable immunity. Sauer believes that the best age to give it is between the seventh and tenth months. If the child has been immunized against diphtheria or smallpox, several months should elapse before pertussis immunization.

It should be remembered that more evidence should be gathered on this procedure before it is adopted as a general

public health measure. Whooping cough is one disease for which the infant has no natural immunity, almost all of the mortality occurs in the first and second years of life, therefore, if the infant can be protected, it is highly desirable. It takes four months for immunity to develop from Sauer's vaccine, therefore, it would be necessary to give it quite early in life. Whether it is wise to immunize young infants in the face of possible reactions remains to be seen.

In regard to older children, or those younger who have been immunized against diphtheria and smallpox, it could be considered. The facts should be laid before the mother; that reactions occur, and that while probably the majority of children will become immune, there is no test at the present time to discover who has become immune and who has not. Therefore, immunity cannot be guaranteed. As it takes four months for immunity to develop, immunizations should not be given during an epidemic.

The injections are given subcutaneously at weekly intervals for three weeks. The initial dose is 1 cc. in each deltoid, the second 1.5 cc. in each triceps, and the third 1.5 cc. in each biceps. This makes a total dosage of 8 cc. The skin should be cleansed with soap, water and alcohol, and the syringe and needle boiled in distilled water for ten minutes.

Reactions when they occur may be general or local with a rise in temperature to 101° F. four to forty-eight hours after injection, and tenderness, redness and induration. Movable, subcutaneous nodules of induration may exist for a month. Usually no treatment of any kind is necessary nor any change in routine of injection.

There are several methods of prophylactic immunization employed for those exposed to the disease. The older vaccines containing 5 to 10 billion killed organisms per cubic centimeter are given subcutaneously in doses of 0.25, 0.5, 1, and 1.5 cc. at intervals of two to three days. Their efficiency is under much dispute.

Frawley has reported good results in the use of undenatured pertussis antigen for prophylaxis. The initial dose is 1 cc. given subcutaneously, followed by 2 cc. every other

day until 6 doses have been given. Human blood serum is used in the culture medium, and there seems to be very little local or general reaction.

Convalescent serum from patients recovering from whooping cough has been used in amounts of 10 cc. for children known to have been exposed to the disease. The evidence in regard to this is indefinite.

Chickenpox and Mumps.—Blood serum from recently convalescent individuals has been used for both these diseases. Their value is not absolutely proven and the indication for such use is infrequent due to the mildness of these infections.

Poliomyelitis.—Kolmer has developed a method of vaccination against poliomyelitis by giving a suspension of monkey spinal cord, from animals receiving an inoculation with sodium ricinolated virus. This is given in three increasing doses at weekly intervals. It has only been used on a few individuals and is not commercially available as yet.

For passive immunity convalescent serum and normal serum have been proposed during epidemics. Convalescent serum might be of value, but it is so limited in amount that it should be confined to the treatment of early cases. Normal serum and whole adult blood have been used in amounts similar to those used in measles immunization. The value of these has not been demonstrated, but they certainly can do no harm.

Rabies.—If a child is bitten or scratched by a dog (cats and monkeys can also have rabies), and the skin is broken, give vaccine if the animal is unknown, disappears, dies in less than ten days, is killed in less than ten days, or develops rabies. If it has a suspicious sickness, begin vaccine and observe. It is not necessary to give vaccine if the dog remains well. Contaminated bites should be cauterized with nitric acid. Head wounds are the most dangerous.

Different preparations are supplied, but all are usually emulsified rabbit cord, infected with a fixed killed virus. They are incapable of producing rabies as a result of the injection. The treatment consists of 14 daily injections given subcutaneously. In cases of extensive injury, or more than a suspicion of rabies, 21 to 28 injections should be employed.

MICHAEL REESE HOSPITAL AND NORTHWESTERN UNIVERSITY
MEDICAL SCHOOL

RICKETS: IS THERE A DIETETIC FACTOR?

THIS baby is seven months old. To all appearances he is normal. I will not take time to go over all points in the physical examination but simply note no abnormalities other than the barest suggestion of beading of the ribs. This is no more marked than in many babies pronounced physically normal. He has no craniotables nor Harrison's groove. He holds his head up well and makes very definite efforts at sitting up, although he does not accomplish the latter with complete facility. His gums are swollen and one of the lower central incisors is just coming through. Possibly in development he may be a few weeks behind what is considered a perfect average. However, the fact that he has been boarded in the hospital ever since his birth may be the explanation. Are these findings sufficient to justify a diagnosis of mild rickets?

The family and past histories are negative.

In previous clinics I have discussed "The Normal Infant" and also "Infant Nutrition." Do not be alarmed. This is no repetition. This baby is being demonstrated as an introduction to the subject of rickets.

During recent years the profession and the public have been almost overwhelmed with literature on rickets. I must confess that I do not quite understand the reason. During my student days when there were no known vitamins, rickets did not assume such dread significance, and it is only recently that we find the term on the lips of every physician and layman. Is it possible that in the background lies the propaganda of interested industries? Or is there really an increase in the incidence of the disease?

I am not going to review the subject this morning in the classical style of conventional etiology, pathology and symptomatology. You are familiar with the present-day tendencies. One must penetrate deep into the wilderness indeed to escape the blaring radio and the bombardment of leaflets extolling the virtues of vitamin D as it exists in cod liver oil, halibut liver oil, salmon liver oil, irradiated ergosterol (*i. e.*, viosterol), milk of cows receiving irradiated yeast in their fodder, and irradiated milk. I will not even discuss the recent findings of Bills of the Mead Johnson Company describing differences in the vitamin D action of cod liver oil and the oil of the tuna. There is still much scientific work to be done. Today I want to discuss the subject from a purely clinical standpoint with special reference to some of my thoughts and observations during the last five years.

Probably every pediatrician has noted that some babies develop signs of rickets in spite of receiving supposedly adequate amounts of vitamin D. These findings are usually ignored and the parents assured that the baby is perfect. I have seen little reference to this phase of the subject in scientific literature. One hears more of it in the "off the record" conversations at the medical meetings.

In view of the tradition that rickets becomes most apparent during periods of rapid growth, I have often asked myself whether the present-day craze for huge babies may not be a hitherto unsuspected factor. In this category does a factor lie in the concentrated high caloric diets now so generally used which may induce a period of unnatural growth? Is it also possible that cod liver oil which on the one hand contains the antirachitic vitamin but on the other increases the size of the subject has a disadvantageous as well as an advantageous effect?

There is also another possibility which for some reason or other has been overlooked by pediatricians, namely the effect of the reaction of the intestine. This latter is the specific study I have been making during the last years and is the one I am going to report today.

In previous publications concerned with infant nutrition we have reported that the addition of 12 per cent lactose to boiled whole cow's milk is generally followed both by an increase in the hydrogen ion concentration and the gram-positive flora of the stool. In other words, there is in some respects a trend toward the stool of the breast-fed. Other sugars studied failed to give similar results. But on the other hand, babies receiving such concentrated high caloric mixtures developed nutritional disturbance presumably from overfeeding.

In 1926 Bergeim reported experiments in albino rats showing a better absorption of calcium when given with lactose than with other carbohydrates. This he attributed to the increase in intestinal acidity following the use of lactose.

During recent year lactic acid milk and other concentrated foods have shown increasing popularity. The addition of acid to cow's milk unquestionably facilitates gastric digestion, but we have shown that the stool remains alkaline. During these years lactose has been practically discarded in infant feeding. Is it possible that the feedings so generally employed fail to acidify the intestine sufficiently to promote proper calcium absorption and in themselves create an increased demand for antirachitics? Can there be an increased incidence of rickets due not only to the caloric content but also to the chemical nature of the formulae used?

In an effort to solve one phase of this problem we have contrasted the effect of a maltose-dextrin preparation with that of lactose upon the development of rickets when the respective carbohydrates were added in equal quantities to diluted cow's milk. The study has been both clinical and metabolic. The present report concerns the clinical observations on 20 infants.

Method.—The infants were admitted to the hospital as soon as possible after birth and kept in a separate room with special nursing care. No vitamin D was given in any known form. Feedings consisted of ordinary certified milk with no vitamin D addition, diluted with distilled water and boiled one minute. The carbohydrates used were a maltose-dextrin

preparation, lactose and beta-lactose. As our previous work had been done with mixtures of whole cow's milk with 12 per cent carbohydrate addition, it was first planned to use such a mixture, but in quantities restricted to the caloric needs of the infants. As will be seen, the results in the first two infants precluded further use of this combination. So that mixture was diluted to one half or two thirds strength as indicated by the patient's age. In such dilution the relation of carbohydrate to protein remained unchanged.

Calcium and phosphorus intake and excretion were determined in the usual type of metabolic experiment. These results will be reported in a subsequent publication.

Clinical observations consisted of monthly physical and roentgenological examinations as well as determinations of blood calcium and phosphorus.

These clinical observations were presented at a recent meeting of the Chicago Pediatric Society* and I will now give them informally.

Results.—The chart (Fig. 158) shows the babies studied with reference to the calendar and the diet. Unfortunately for scientific work we had to take the babies when we could get them. Babies 1 and 2 are the only ones receiving the original mixture of whole milk with 12 per cent carbohydrate addition, one lactose, the other maltose-dextrin. All the others received dilutions of the above mixture with the exception of babies 17 and 18, who received whole cow's milk with no addition during most of the period, and babies 10 and 13 who received breast milk.

In this chart we have graded each baby, considering 10 as perfect. The grades were reached by considering physical, roentgenological and blood chemical examinations as well as the reports and impressions of impartial nurses and house physicians in charge of the infants. It will be seen that in this series the babies on lactose showed a very slight superiority. However, it must be remembered that only 20 babies were studied. Observations were extended over four years

* December 18, 1934.

and conditions and seasons were not comparable. Also the rating was to a considerable extent subjective. Conclusions should not be definite until the chemical analyses are completed.

While there may have been a slight clinical difference between the babies receiving lactose and those on maltose-dextrin, the striking finding was the low incidence of any appreciable

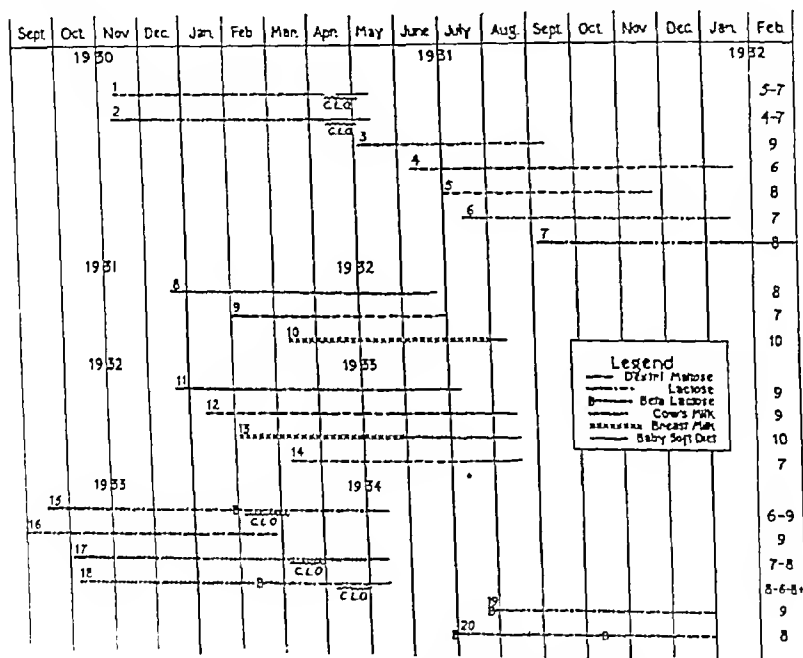

Fig. 158.—The cases grouped according to the length of time under observation, the calendar and the diet prescribed.

degree of rickets in either group. Far more important than differences in the type of carbohydrate used was the difference shown between infants receiving cow's milk with high carbohydrate, cow's milk with no addition and cow's milk diluted and with carbohydrate addition. While under no circumstances questioning the importance of vitamin D, one feels that in these findings there is a suggestion of a dietetic element not as yet clearly defined.

The chart (Fig. 159) shows the findings in baby 13, who received breast milk and served as a control; in babies 17 and 18 who received whole cow's milk and in babies 1 and 2 who received whole cow's milk with 12 per cent carbohydrate. The chart shows the clinical findings as well as the results of monthly x-ray and blood chemical examinations.

The contrast in the findings is startling. It is only fair to state that babies 1 and 2 were twins, came to us somewhat

later than the other infants, and were slightly rachitic upon admission. All these factors probably played a part in determining the severity of the rickets which was by far more pronounced than in any of the babies studied. But at any rate there was no spontaneous improvement in the condition. We did not feel justified in repeating the experiment though at the conclusion of the period of observation a brief treatment

with cod liver oil brought the findings rapidly to normal. The contrast between these two babies and the breast-fed is certainly striking. The two babies receiving whole cow's milk, while not showing such distinctive blood and x-ray findings, averaged between the two groups on clinical examination.

The chart (Fig. 160) contrasts babies 8 and 9 and 11 and 12, two receiving lactose mixtures and two maltose-dextrin. The findings here are typical of the majority of the infants. To

our great surprise most of the infants went through the six months' observation period with little abnormality on x-ray examination and with normal blood chemistry and phosphorus. Physical examination apparently proved a more delicate diagnostic index than laboratory findings, for most of the infants at some time showed a mild rosary or Harrison's groove. But these findings were scarcely more marked than in some infants who had received routine treatment with cod liver oil. Again during the observations a mild rosary and Harrison's groove

might appear for a time and then improve spontaneously. Certainly not all the improvement seen in clinics and private practice during the first six months can be attributed to antirachitic prophylactics and remedies. Craniotabes proved perplexing. It occurred in some degree in all the infants during the early weeks. Then it disappeared. However, in the few babies developing true rachitic findings during and after the fifth month it reappeared. Apparently it is of no significance until this later period.

Fig. 161.—Same as Fig. 160 on diets of milk with the addition of beta-lactose.

The chart (Fig. 161) contrasts babies 19 and 20. They were both started on a milk mixture with beta-lactose addition, but later baby 20 received maltose-dextrin for some months. Here again the findings are similar to those in the preceding chart. Baby 15 is also shown in this chart, illustrating the effect of cod liver oil. This infant was started on a mixture of two thirds milk with low carbohydrate. He was the only infant on any milk dilution to develop pronounced clinical

symptoms. Here the striking influence of cod liver oil is shown. But what is even more surprising is the relatively small amount of the oil necessary. From the middle of February 2 teaspoonfuls were given daily. By March the laboratory and clinical signs showed decided improvement. By April the baby had two teeth. In this infant, simultaneously with the giving of the oil, a gram-negative flora changed to gram-positive and was so maintained after the oil was discontinued.

Fig. 162.

In other attempts we were not able to obtain the same effect of the oil upon the flora.

Height and Weight.—All of the babies studied were definitely below the standards given as normal in the accepted tables. Even those who were roentgenologically and chemically nonrachitic and who seemed in perfect nutritional condition weighed as much as 2 pounds below the accepted average. Here, as in the infant just demonstrated, one is uncer-

tain whether the finding is due to "hospitalism" or to the lack of cod liver oil. If cod liver oil has the faculty of hanging several apparently unnecessary pounds on a normal infant, it may have an injurious as well as a beneficial effect.

Caloric Intake.—The table (Fig. 162) shows the average caloric intake of each baby over periods of two weeks each. The table affords a comparison between the energy consumption of the majority of infants who showed very mild clinical rickets and those few showing no signs at all. It also shows the effect upon the caloric intake of increasing the concentration of the diet.

During the first few weeks the findings can be disregarded due to adjustments of the diet. Looking at the table as a whole, one sees at first no consistency in the findings. Or at any rate, there is no correlation in any one infant between the severity of the signs and the caloric intake. On the other hand, we have as controls baby 10 who was a perfect example of the breast-fed and baby 19 who was the most perfect clinically of the artificially fed. In these babies the caloric intake was not only decidedly less than in the others, but also showed a gradual reduction during each succeeding period. On the other hand, baby 11 who was practically normal clinically took a high amount. This baby was very small and seemed to require the amount given even for slight gain. He remained the smallest of the group at the time of his discharge from the hospital. Again baby 13, a breast-fed infant, took a surprisingly high diet. He was definitely below normal nutritionally and suffered for a time from generalized furunculosis. While it is difficult to formulate definite conclusions, one gets a certain clinical impression that the rachitic infants generally consumed more calories than were necessary for a normal gain in weight; or at any rate, they continued a high caloric consumption over a longer period of time with no spontaneous reduction in intake as did babies 10 and 19. For instance, baby 20 showed definitely more positive findings than did baby 19. The difference in caloric intake is apparent.

I always had the impression that babies on concentrated

diets automatically restricted their caloric intake to their requirements. This is definitely not so. Babies 1 and 2 on the most concentrated diet were frequently hungry and dissatisfied with the quantities offered. It will be seen in every case that when the diet was concentrated to higher caloric value, the infant invariably increased his caloric intake to a quantity greater than was necessary for a gain in weight. He did not adjust his food intake to his caloric need. In other words, concentrated diets lead to overfeeding. This may be of importance in the long continued usage of such formulae.

Relations of the Elements of the Diet.—Rickets developed in decreasing severity in diets as follows:

Whole cow's milk with 12 per cent carbohydrate.

Whole cow's milk.

Whole cow's milk with 12 per cent carbohydrate appropriately diluted.

Breast milk.

The milk mixtures uniformly used showed a relation of carbohydrate to protein approximating that in human milk. With the exception of those in which overfeeding played a rôle, these formulae even in the absence of vitamin D were accompanied by rickets of only a mild type. These observations should be repeated with other formulae. Possibly the proportions of the mixtures may have been of some importance.

Growth Curves.—The chart (Fig. 163) shows the weight curves of four infants. One received cow's milk with 12 per cent carbohydrate; the second, a dilution of the above; the third, cow's milk with no addition, and the fourth, breast milk. Here again we see another manifestation of the different effects of these formulae. All these babies were subjected to monthly determinations of blood calcium and phosphorus as well as to repeated periods on the metabolism bed. In spite of these interruptions the breast fed infant pursued a relatively smooth and consistent course. The baby receiving the milk dilution was next. The baby on undiluted cow's milk fell below the standards of the others while the one receiving the high caloric mixture had a turbulent time. The

latter curve is also interesting in that it shows that a high caloric diet does not necessarily lead eventually to a large baby. While the growth of this infant was first rapid and far above normal, the curve eventually flattened out to approach the others at about the six-month period. Excessive feeding then could not obviate nature's plan for the eventual weight of this infant and he had to dispose of his extra food as best he could.

Fig. 163.—The weight curves on diets of breast milk, cow's milk with 12 per cent carbohydrate, dilutions of the latter, and undiluted whole cow's milk.

If there is a dietetic factor in the prevention of rickets it probably is in the combination of proper calories and proper proportion of food elements existing in ideal form in human milk.

Cod Liver Oil.—The fact that most of the infants went through six months in a hospital with no cod liver oil, no known source of vitamin D or ultraviolet light, and with rachitic findings of only a very mild type cannot be overlooked. Again the relatively small amount of cod liver oil

necessary to right the condition raises two questions. Is the effectiveness of the oil influenced by physicochemical conditions in the intestine? In baby 15 (Fig. 161) the laboratory and clinical response to relatively small amounts of the oil was striking. Or is it true that cod liver oil and vitamin D are prescribed in unnecessary quantities and that we physicians and our patients are being exploited?

Medical men have undoubtedly known that many babies will not develop rickets during the first six months, even if given no antirachitic. They have undoubtedly suspected that antirachitics may be given in unnecessary quantities and they have probably suspected that determinations of blood calcium and phosphorus as well as α -ray examinations are not reliable indices as to the existence of rickets. But for some reason or other the whole subject has been shrouded in more or less silence.

Summary.—To summarize this clinic, we have specifically raised the question as to why some babies develop signs of rickets in spite of a supposedly adequate dosage of vitamin D. We have suggested that one factor might lie in the present-day methods of feeding which seem to us to lay undue emphasis upon the desirability of maximal size values.

We have also raised the question and entered into a scientific study of the importance of the chemical effect upon the infant's intestine of some of the diets commonly used. If calcium and phosphorus are absorbed more readily from an acid intestine, an increased incidence of rickets might be ascribed to present-day methods of feeding because most of the popular formulae do not lead to high intestinal acidity. The only carbohydrates which seem to do this are lactose and beta-lactose and up to recently these have not been used extensively.

In the 20 babies studied clinically with special reference to the development of rickets, there seemed little difference between those receiving maltose-dextrin and those receiving lactose. Those on lactose and beta-lactose may have shown slight clinical superiority but such conclusion is tentative until further chemical studies are completed.

Much more apparent were the differences shown by babies receiving whole boiled cow's milk with 12 per cent carbohydrate addition, dilutions of this mixture, whole boiled cow's milk with no carbohydrate addition and breast milk. As none of these babies received antirachitics, it is presumable that a dietetic factor was also involved. Excluding the influence of the degree of acidity of the intestinal contents, this dietetic factor probably lies in the caloric content, concentration, nature and percentages of the food elements in the formula. Certainly in those few infants developing signs of rickets the severity of the condition in a general way paralleled the concentration of cow's milk and the excess of carbohydrate in the formula.

In this study a number of incidental observations were of interest.

It was somewhat out of the ordinary to note that most of the babies could spend six months in a hospital ward, receive no antirachitics and show rickets of only the very mildest type or often no rickets at all. In the babies with positive signs, cod liver oil was effective in smaller doses and over a shorter period of time than I had thought necessary.

In this study physical examination proved a far more delicate method of determining the early development of rickets than did the x-ray or determinations of blood calcium and phosphorus. Craniotabes was of little diagnostic significance before the fourth or fifth month.

- seasonal incidence in Phila-
delphia, *July*, 151-157
- thrombosis, angina pectoris and,
differentiation, *Jan.*, 1085
- treatment, *Nov.*, 873-880, 887
- Cortical hormone therapy in Addi-
son's disease, *Sept.*, 392-396
- Culture medium, Löwenstein's, in
tuberculosis, *Nov.*, 722
- Cutaneous. See *Skin*.
- Cysts, nabothian, *Sept.*, 349
- tubal, in female gonorrhea, *Nov.*,
920
- DALRYMPLE'S sign, *Jan.*, 1208
- Deficiency anemias, *July*, 37
- diseases, methods of production,
Sept., 468
- occurrence of, *Sept.*, 466, 474
- Dehydration in inoperable cancer,
treatment, *July*, 202
- Delirium in pneumonia, treatment,
July, 14
- Dental field, pain in, *Jan.*, 1057-1066
- Dermatopolyneuritis, *Nov.*, 957
- Dermatoses, pruritus of, *Nov.*, 979
- Deryl-Hart apparatus, *July*, 31
- Diabetes, eye symptoms, *Jan.*, 1231
- in children, insulin in, *Nov.*, 791-805
- management, *July*, 273-286
- Diabetic coma in children, treatment,
Nov., 800
- treatment, *Jan.*, 1268
- Diabetic polyneuritis, *Nov.*, 956
- Diaphragmatic hernia, anginal pain
in, *Jan.*, 1083
- pleurisy, abdominal pain in, *Jan.*,
1115
- Diarrhea of infants and children,
apple diet in, *July*, 301-305
- Diathermy in gonorrhea of cervix,
Nov., 914
- Diathesis, exudative, *July*, 326
- Dibothriocephalus latus anemia, *July*,
64, 65
- Dick test, *Jan.*, 1285
- Diet, apple, in diarrhea of infants and
children, *July*, 301-305
- "bleeding" and "clotting," *Nov.*,
989-999
- diabetic, for children, *July*, 274
- in angina pectoris, *Jan.*, 1097
- in coronary thrombosis, *Nov.*, 876,
887
- in pneumonia, *July*, 15, 17
- Karell, *July*, 174
- ketogenic, in epilepsy, *July*, 263
- Dietary treatment of hypertension,
July, 144
- of inoperable cancer, *July*, 197
- of nephritis with vascular and
cardiac complications, *July*,
175
- of secondary anemias, *July*, 97
- Digitalis in nephritis with vascular
and cardiac complications, *July*,
174
- Digitalization in pneumonia, *July*, 14
- Diphtheria bacillus, rapid culture
method, *Nov.*, 736
- Schick test, *Jan.*, 1282
- toxic for immunization, *Nov.*, 736;
Jan., 1281
- with heart involvement, *Nov.*, 737
- Diphtheritic polyneuritis, *Nov.*, 955
- Diuretics in nephritis with vascular
and cardiac complications, *July*, 174
- Diverticula, Meckel's, *Sept.*, 372, 373
- of small intestine, *Sept.*, 372
- Diverticulitis, *Sept.*, 374
- perforation in, management, *Sept.*,
407
- Drugs, convulsant, poisoning in chil-
dren by, *July*, 256
- in causation of pernicious leuko-
penia, *July*, 110-118
- poisoning by, treatment, *Jan.*, 1268
- Dwarfism, pituitary, *Nov.*, 825, 826
- Dyscrasia, blood, four clinical types of
jaundice arising from, *Sept.*, 545-550
- Dysinsulinism, *July*, 233
- Dyskinesia, biliary, *Nov.*, 669, 673
- Dysmenorrhea, *Jan.*, 1132
- Dyspareunia, *July*, 267, 268

- Dyspepsia in gallbladder disease, *Nov.*, 642
- Dystrophy, adiposogenital, *Nov.*, 826-830
- EAR drops, *Jan.*, 1042
 drum, blue, *Jan.*, 1048
 paracentesis of, *Jan.*, 1042
 rupture of, traumatic, *Jan.*, 1054
 foreign bodies in, pain due to, *Jan.*, 1052
- Earache, reflex, *Jan.*, 1055
 treatment, *Jan.*, 1039-1055
- Eclamptic uremia, acute, *July*, 236, 238
- Ectropion of cervix, *Sept.*, 349
- Eczema, contact, *July*, 319-324
 in infancy and childhood, *July*, 325-331
 of ear, *Jan.*, 1050
- Edema, stasis, in thrombophlebitis, *Sept.*, 542
 in varicose veins, *Sept.*, 538
- Elliott heat treatment of cervicitis, *Sept.*, 353
- Embolectomy, *July*, 168
- Embolism, air, in artificial pneumothorax, *Nov.*, 908
 of aorta and its larger branches, *July*, 159-170
 pulmonary, simulating coronary disease, *Jan.*, 1079
- Embryoma of testis, *Sept.*, 599
- Emotional storm, severe abdominal pains following, *Sept.*, 399-402
- Empyema complicating pneumonia, surgical management, *July*, 30-33
- Encephalitis, epidemic, eye symptoms, *Jan.*, 1228
 postvaccinal, *Jan.*, 1280
- Encephalopathy, hypertensive, *July*, 238
- Endocrine therapy. See *Hormone therapy.*
- Enterocolitis, ulcerative, regional, *Sept.*, 411-422
- Enuresis in childhood, causes and treatment, *July*, 287-294
- Epilepsy, idiopathic, *July*, 259-264
- Epileptiform convulsions, *July*, 260
- Epiphyses, separation of, *Nov.*, 830
- Epitheliomas of arm simulating endothelioma, sarcoma and sporotrichosis, *Sept.*, 605-610
 of ear, *Jan.*, 1054
- Epituberculosis, roentgen findings, *Nov.*, 715
- Erb's sign in tetany, *July*, 255
- Erosion of cervix, *Sept.*, 349
 cautery treatment, *Sept.*, 354
- Erysipelas of auricle, *Jan.*, 1051
- Erythematous lupus, acute disseminated, visceral lesions of, *July*, 333-346
- Erythredema polyneuritis, *Nov.*, 957
- Estrin in menopause, *July*, 220-224
- Evaporated milk for infants, *Nov.*, 787
- Eversion of cervix, *Sept.*, 349
- Ewing's tumor, roentgen therapy, *Sept.*, 602
- Exophthalmic goiter, eye symptoms, *Jan.*, 1204
- Exophthalmos, *Jan.*, 1205
- Extremities, increased length, in arteriovenous fistula, *Sept.*, 526, 528
 venous diseases, *Sept.*, 535-543
- Exudative diathesis, *July*, 326
- Eyegrounds, examination, *Jan.*, 1198
- Eyes, examination, *Jan.*, 1189
 in acute disseminated lupus erythematosus, *July*, 337
 symptoms, diagnostic value in general disease, *Jan.*, 1187-1239
- Eyestrain, headaches due to, *Jan.*, 1202
- FACIAL neuralgia, relief of, *Jan.*, 1017-1028
- Favus of scalp, *Jan.*, 1249
- Febrile diseases in infants, convulsions due to, *July*, 252
- Feeding, infant, difficult cases, *Nov.*, 785-789
- Feet, painful, relief of, *Jan.*, 1067-1075
- Ferments, pancreatic, *Nov.*, 683
- Fever in acute appendicitis, *July*, 193
 therapy, *Sept.*, 585-595
 in chorea in children, *Sept.*, 591; *Nov.*, 771-784
- Fibrositis, chronic, inactivation by jaundice, *Sept.*, 573-583
- Fistula, arteriovenous, congenital, *Sept.*, 525
 gastrojejuno-colic, anemia with, *July*, 67
 of small intestine, *Sept.*, 377
- Flush, menopausal, *July*, 215
- Follutein, *Nov.*, 818
- Foods, vitamin content, advisability of increasing, *Sept.*, 472
- Foot, march, *Jan.*, 1075
 strain, *Jan.*, 1073
- Foreign bodies in bronchus causing obstruction, *Sept.*, 457
 in ear, pain due to, *Jan.*, 1052
- Fractures of ribs, pain in, simulating coronary disease, *Jan.*, 1081
 of skull, eye symptoms, *Jan.*, 1238
- Fröhlich's syndrome, *Nov.*, 826-830

- Frostbite of ear, *Jan.*, 1053
Fundus, eye, examination, *Jan.*, 1201
Fungi in external ear, *Jan.*, 1050
Furunculosis of ear, *Jan.*, 1049
- GAENSLER'S sign in sacro-iliac lesions, *Jan.*, 1036
Galaetose tolerance test, *Jan.*, 1167
Gallbladder disease, biliary drainage in, diagnostic value, *Nov.*, 679
therapeutic value, *Nov.*, 687
diagnosis, *Nov.*, 641-648
metabolic disturbances in, *Nov.*, 664
pancreatic disease associated with, *Nov.*, 664
symposium on, *Nov.*, 639
symptoms, atypical, *Nov.*, 649-675
dyskinesia, *Nov.*, 669, 673
functional disturbances, *Nov.*, 666
treatment, *Nov.*, 672
stasis, *Nov.*, 669
vertigo, *Nov.*, 653
Gallstones. See *Cholelithiasis*.
Gas pains, postoperative, *Jan.*, 1125
Gasserian ganglion, sensory root avulsion, for trigeminal neuralgia, *Jan.*, 1028
Gastrectomy, anemia following, *July*, 67
Gastric juice in relation to pernicious anemia, *July*, 41
lavage for diagnosis of tuberculosis, *Nov.*, 721
resection for peptic ulcer, recurrences after, *Sept.*, 451
tetany, *July*, 242
Gastroduodenostomy, lateral, for peptic ulcer, recurrence after, *Sept.*, 434
Gastro-enterostomy for peptic ulcer, recurrent and anastomotic ulcer after, *Sept.*, 441
Gastro-intestinal manifestations of systemic disease and their differential diagnosis, *Jan.*, 1251-1263
tract in development of deficiency diseases, *Sept.*, 468
Gastrojejunal ulcer following gastro-enterostomy, *Sept.*, 442
Gastrojejunal fistula, anemia with, *July*, 67
Gastrotomy, anemia following, *July*, 67
Giant-cell tumor of bone, roentgen treatment, *Sept.*, 601
Giardia intestinalis in bile, *Nov.*, 680
Gifford's sign, *Jan.*, 1208
Ginger paralysis, *Nov.*, 953
Glaucoma, headache in, *Jan.*, 1203
Glossitis, atrophic, nutritional factors, *July*, 59
Glossopharyngeal neuralgia, relief of, *Jan.*, 1028
Goiter, exophthalmic, eye symptoms, *Jan.*, 1204
Gonadal insufficiencies, pituitary, *Nov.*, 832
Gonococcal urethritis, fever therapy, *Sept.*, 588
Gonorrhea in women, *Nov.*, 911-914
treatment, *Nov.*, 914-926
Gonorrheal arthritis, fever therapy, *Sept.*, 551-559, 589
Gout, postoperative, acute, identification of, *Sept.*, 560-566
prevention and treatment, *Sept.*, 566-573
Gradenigo's syndrome, *Jan.*, 1046
Graham test in gallbladder disease, errors in interpretation, *Nov.*, 678
Grand mal, *July*, 260
Granulocytoclastic crisis, *July*, 115
Granulomata of ear, *Jan.*, 1054
Graves' disease, eye symptoms, *Jan.*, 1204
Growth in children, nature and rational appraisal of, *July*, 307-317
Gynecological lesions, pain in, *Jan.*, 1122, 1131
- HALLUX rigidus, *Jan.*, 1074
Hartmann's solution in diabetic coma, *Nov.*, 803
Head injuries, eye symptoms, *Jan.*, 1238
Headache due to migraine, relief of, *Jan.*, 1015
eyestrain and, *Jan.*, 1202
in brain tumor, *Jan.*, 1203
in glaucoma, *Jan.*, 1203
menopausal, *July*, 217
pituitary, *Nov.*, 833
waking, *Jan.*, 1202
Heart block, convulsions and unconsciousness in, *July*, 243
frequency, *July*, 123-129
treatment, *July*, 129-131
disease, gastro-intestinal manifestations, *Jan.*, 1261
in pregnancy, management, *Nov.*, 893-899
failure complicating chronic glomerular nephritis, *July*, 171
lesions of, in diphtheria, *Nov.*, 737
Hemolytic crisis, acute, *Sept.*, 548, 549
jaundice, *Sept.*, 545, 549
Hemoptysis in pulmonary tuberculosis, management, *Nov.*, 901-904

- Hepatitis, biliary drainage in, therapeutic value, *Nov.*, 687
- Hernia, diaphragmatic, anginal pain in, *Jan.*, 1083
- Herpes zoster of auricle, *Jan.*, 1052
- Hexuronic acid, *Sept.*, 482
- Hilar nodes, tuberculous, *Nov.*, 711
- Hodgkin's disease, abdominal, *Sept.*, 423-427
- itching in, treatment, *Nov.*, 967-970
- Homosexuality, *Nov.*, 938
- Hormone therapy in Addison's disease, *Sept.*, 392-396
- in functional metrorrhagia in young women, *Sept.*, 361
- in menopause, *July*, 220, 221
- in pituitary disorders, *Nov.*, 818
- in secondary anemia, *July*, 100
- Hunt's zoster auricular, *Jan.*, 1052
- Huntoon's antibody solution in pneumonia, *July*, 6
- Hydrocephalus, convulsions due to, *July*, 251, 254
- Hydrosalpinx, gonorrheal, *Nov.*, 920
- Hyperinsulinism, *July*, 233
- Hypertension, *July*, 133
- arteriosclerosis with, *July*, 139
- cold test in, *Sept.*, 518
- complicating chronic glomerular nephritis, *July*, 171

- Infections, acute, in infants, convulsions due to, *July*, 251, 252
- resistance to, vitamins and, *Sept.*, 471
- roentgen treatment, *Sept.*, 597
- Infectious diseases of childhood, immunization against, *Nov.*, 731-744; *Jan.*, 1277-1290
- Inflammation of small intestine, *Sept.*, 378
- Inflammatory conditions, roentgen treatment, *Sept.*, 597
- disease, pelvic, gonorrheal, *Nov.*, 920
- Inflations in acute serous otitis media, *Jan.*, 1042
- Influenza meningitis, *Nov.*, 768
- Insomnia in hypertension, treatment, *July*, 144
- menopausal, *July*, 218
- Insulin in diabetes of childhood, *July*, 277; *Nov.*, 791-805
- Intercourse, unsatisfactory, treatment of, *July*, 267
- Intestinal anastomosis, multiple, macrocytic anemia following, *July*, 67
- Intestine, small, lesions of, other than peptic ulcer, *Sept.*, 365-382
- Intussusception, *Sept.*, 378
- Iron therapy in secondary anemias, *July*, 93-96
- Irritable colon, pain in, *Jan.*, 1123, 1127
- Itching, *Nov.*, 971-980
- in Hodgkin's disease, treatment, *Nov.*, 967-970
- treatment, *Nov.*, 980-987
- JACKSONIAN convulsions, *July*, 260
- Jaeger's test types, *Jan.*, 1193
- Jake paralysis, *Nov.*, 953
- Jaundice, catarrhal, biliary drainage in, therapeutic value, *Nov.*, 685
- diagnosis and medical management, *Jan.*, 1163

- Jaundice, four clinical types arising from atypical blood dyscrasia, *Sept.*, 545-550
 hemolytic, *Sept.*, 545-549
 in abdominal Hodgkin's disease, *Sept.*, 425
 in cholelithiasis, *Nov.*, 644
 inactivation of chronic infectious arthritis and fibrositis by, *Sept.*, 573-583
 Jejunal ulcer following gastro-enterostomy, *Sept.*, 442
 Joins, diseases of, *Sept.*, 551-583
 Juvenile diabetes, *July*, 273-286
- *KARELL diet, *July*, 174
 Kerion of scalp, *Jan.*, 1247, 1248
 Ketogenic diet in epilepsy, *July*, 263
 Kettering hypertherm, *Sept.*, 585
 Kidney, carcinoma of, roentgen treatment, *Sept.*, 601
 disorders, gastro-intestinal manifestations, *Jan.*, 1262
 in pregnancy, prevention, *July*, 295-299
 Koerner's syndrome, *Jan.*, 1052
 Kolmer's serum in poliomyelitis prophylaxis, *Nov.*, 742; *Jan.*, 1290
 Kramm's approach to parapharyngeal abscess, *Jan.*, 1159
 Krueger's pertussis vaccine, *Nov.*, 738, 739
- LACERATIONS of cervix, *Sept.*, 348
Lamblia intestinalis in bile, *Nov.*, 680
 Laryngeal neuralgia, superior, relief of, *Jan.*, 1029
 Laryngitis, earache in, *Jan.*, 1055
 Lavage, gastric, for diagnosis of tuberculosis, *Nov.*, 721
 Lead neuritis, *Nov.*, 953
 poisoning in children, convulsions from, *July*, 257
 Leprous polyneuritis, *Nov.*, 958
 Leukemia, chronic myelogenous, *Sept.*, 546, 549
 Leukopenia, pernicious, *July*, 103-122
 Leukorrhea, *Sept.*, 349
 Lipemia, retinal, *Jan.*, 1233
 Liver, active principle, *July*, 49, 75
 storage of, *July*, 57, 58
 extract, intra-osseous injection, in pernicious anemia, *July*, 50
 extrinsic factor, *July*, 49, 51
 functional tests, *Jan.*, 1165
 therapy in secondary anemias, *July*, 96
 Liver-stomach mixtures in pernicious anemia, *July*, 49
- Lobar pneumonia. See *Pneumonia*.
 Lobectomy for bronchiectasis, *Jan.*, 1175
 Löwenstein's culture medium in tuberculosis, *Nov.*, 722
 Lumbago, relief of, *Jan.*, 1033-1038
 Lumbar puncture in pseudo-uremic convulsions, *July*, 240
 Lung, abscess of, bronchial obstruction in, *Sept.*, 456, 462
 complicating pneumonia, *July*, 33, 34
 carcinoma of, bronchial obstruction in, *Sept.*, 456
 tuberculosis of. See *Tuberculosis, pulmonary*.
 Lupus erythematosus, acute disseminated, visceral lesions of, *July*, 333-346
 of scalp, *Jan.*, 1242
 miliaris disseminatus faciei, *Sept.*, 617
 Lyon's test in gallbladder disease, diagnostic value, *Nov.*, 679
- MACULA lutea, *Jan.*, 1200
 Malignant hypertension, *July*, 134
 tumors, roentgen treatment, *Sept.*, 598-603
 Mantoux tuberculin test, *Nov.*, 703
 March foot, *Jan.*, 1075
 Marmite in pernicious anemia, *July*, 52, 54, 55, 56, 73
 Marschik's approach to parapharyngeal abscess, *Jan.*, 1158
 Massage, prostatic, *Jan.*, 1181, 1184
 Mastoiditis, pain of, relief, *Jan.*, 1044-1047
 Maxillary sinus infection, pain in, *Jan.*, 1062
 McBurney's point symptoms in appendicitis, *July*, 190
 Measles, immunization, *Nov.*, 734, 735; *Jan.*, 1287
 Meckel's diverticulum, *Sept.*, 372, 373
 Mediastinitis, pain in, simulating coronary disease, *Jan.*, 1079
 Memory impairment, menopausal, *July*, 217
 Meningitis, *Nov.*, 751-769
 Menopause, symptoms and treatment, *July*, 205-226
 Menorrhagia, menopausal, *July*, 214
 Menstrual disturbance, functional, metrorrhagic type, in young women, *Sept.*, 359-364
 Mental attitude in inoperable cancer, *July*, 196
 disorders, puerperal, *Nov.*, 927-941
 Mercury polyneuritis, *Nov.*, 955

- Metabolic disturbances in gallbladder disease, *Nov.*, 664
 of pituitary gland, *Nov.*, 832
 Middle ear disease, pain in, *Jan.*, 1041
 Migraine, relief of, *Jan.*, 1015
 Miliary tuberculosis, roentgen findings, *Nov.*, 712
 Milk, evaporated, for infants, *Nov.*, 787
 Moebius' sign, *Jan.*, 1208
 Moro tuberculin test, *Nov.*, 703
 Mosher's approach to parapharyngeal abscess, *Jan.*, 1158
 Motor education, corrective, in birth injuries and allied problems, *Nov.*, 807-815
 Mouth care in pneumonia, *July*, 16
 Mucous colitis, *Jan.*, 1123, 1128
 membrane of mouth, atrophy of, *July*, 59
 Mumps, *Nov.*, 736
 immunization, *Jan.*, 1290
 Myoma of small intestine, *Sept.*, 371
 Myringotomy, *Jan.*, 1042
- NABOTHIAN cysts, *Sept.*, 349
 Nausea in acute appendicitis, *July*, 186, 193
 in inoperable cancer, treatment, *July*, 200
 Neosynthalin as insulin substitute, *Nov.*, 803
 Nephritis, chronic glomerular, with mild nephrosis, hypertension, heart failure and pericarditis, *July*, 171-176
 eye symptoms, *Jan.*, 1235
 Nephrosis, amyloid, proteosuria in, *July*, 177-184
 complicating chronic glomerular nephritis, *July*, 171
 Nervous system, syphilis of, fever therapy, *Sept.*, 590
 vegetative, rôle in climacteric, *July*, 210
 Neufeld reaction for pneumococcus types, Sabin's technic, *July*, 3, 4
 Neuralgia, dental causes, *Jan.*, 1063
 glossopharyngeal, relief of, *Jan.*, 1028
 laryngeal, superior, relief of, *Jan.*, 1029
 occipital, relief of, *Jan.*, 1030
 Sluder's, relief of, *Jan.*, 1031
 trigeminal, relief of, *Jan.*, 1017-1028
 Neurasthenia, traumatic, *Nov.*, 838, 839
 Neurectomy, retrogasserian, for trigeminal neuralgia, *Jan.*, 1028
- Neuritis, multiple. See *Polyneuritis*.
 optic, in brain abscess, *Jan.*, 1215
 Neurological manifestations of pernicious anemia, with treatment, *July*, 79-89
 Neuropsychoses, menopausal, *July*, 216
 puerperal, *Nov.*, 927-941
 Nevi, spider, *Sept.*, 536
 Newborn, immunity in, *Nov.*, 733
 Night blindness in gastro-intestinal disease or abnormality, *Sept.*, 468, 469
 Nitroglycerin in angina pectoris, *Nov.*, 882, 883; *Jan.*, 1099
 Nona, eye symptoms, *Jan.*, 1228
 Nutritional anemia, *July*, 37-77

SYMPOSIUM ON RECENT ADVANCES IN TREATMENT

The following clinics are included in this Symposium:

Paul D. White and R. Earle Glendy: RECENT ADVANCES IN THE TREATMENT OF HEART DISEASE.

Soma Weiss: RECENT ADVANCES IN THE TREATMENT OF ARTERIAL HYPERTENSION.

Chester S. Keefer: THE TREATMENT OF GONOCOCCAL ARTHRITIS, RHEUMATOID ARTHRITIS AND GOUT.

J. H. Means: TREATMENT OF DISEASES OF THE THYROID.

Conrad Wesselhoeft: TREATMENT OF SCARLET FEVER AND DIPHTHERIA.

LeRoy D. Fothergill: SOME RECENT ADVANCES IN VACCINES AND SERUMS: A REVIEW.

Joe Vincent Meigs: RECENT ADVANCES IN MEDICAL GYNECOLOGY.

Abraham Colmes: RECENT ADVANCES IN THE TREATMENT OF HAY FEVER AND ASTHMA.

Edward S. Emery, Jr.: RECENT ADVANCES IN DIETOTHERAPY.

CLINIC OF DRS. PAUL D. WHITE
AND R. EARLE GLENDY

FROM THE CARDIAC CLINICS AND LABORATORY OF THE MASSACHUSETTS GENERAL HOSPITAL

RECENT ADVANCES IN THE TREATMENT OF HEART
DISEASE

INTRODUCTION

DURING the past decade several significant advances have been made in the treatment of heart disease, probably more than in any previous decade. We have selected for presentation herewith, 5 cases, each illustrating one of the more important new therapeutic measures. In the order of discussion these five measures are quinidine therapy, the use of salyrgan or mercupurin, paravertebral alcohol injection, total thyroidectomy and pericardial resection. They are important adjuncts in treatment but by no means replace any of the reliable older methods of cardiac therapy which include rest, restriction of fluids and diet, the proper use of digitalis, of vasodilator drugs, and of diuretics by mouth, and the cardiac bed and Southey tubes, merely to mention the more important time-honored methods.

One other new therapeutic measure which deserves honorable mention at least, even if not so important as those that are presented in detail in this report, is the administration of theophyllin-ethylene-diamine (ordinarily called aminophyllin, euphyllin, or metaphyllin) in the relief of Cheyne-Stokes respiration and obstinate recurrent angina pectoris (especially at rest). In such cases rapid and striking relief may sometimes follow the administration of $7\frac{1}{2}$ grains (2 cc. ampule) of aminophyllin intramuscularly, or 4 grains (10 cc. ampule) intravenously, or less satisfactorily $1\frac{1}{2}$ to 3 grains by mouth, two to five times daily.

QUINIDINE THERAPY

Caso I.—J. L., a Jewish boy aged nineteen years, was admitted to the Massachusetts General Hospital on February 28, 1935, complaining of rapid irregular palpitation and some vomiting of four months' duration. He had had whooping cough and measles in childhood. In May, 1925, several months after an infection with fever and vomiting, he was seen by us and found to have rheumatic heart disease, with well-marked cardiac enlargement, mitral stenosis, aortic regurgitation, and a normal rhythm with a rate of 96 beats per minute. In June, 1925, a tonsillectomy was done. In the fall of 1925, on account of persistent signs of rheumatic activity (increased temperature, pulse, and white blood cell count), he was put to bed and kept there for about six months, during which time he continued to have a rapid pulse rate, at times as high as 140. From June, 1926 to November, 1934 he felt fairly well, except for an occasional respiratory infection, and with restricted activity was able to attend school and lead a fairly normal life. His heart gradually increased in size, but the rhythm remained normal. During November, 1934, following a cold, he noticed, for the first time, rapid irregular palpitation. He was digitalized at this time and given a maintenance dose of digitalis. For the next three months he did not feel well. On the days when the palpitation was most noticeable he felt weak and often vomited almost everything eaten. Early in December, 1934 he spat $\frac{1}{2}$ ounce of bright red blood, and two weeks later again raised the same amount of blood. From that time until his admission to the hospital, he was confined to bed and chair except for an occasional short walk. The distressing palpitation continued. There was no dyspnea, orthopnea, or edema. His physician referred him to the hospital because of a persistently rapid pulse rate, which did not respond even to large doses of digitalis and small doses of quinidine at home.

Physical examination showed a fairly well nourished, somewhat pale young man with anxious facies sitting propped up in bed. Breathing was slightly rapid. There were rapid irregular arterial pulsations in the neck. The pupils were somewhat dilated but reacted normally. There were a few slightly enlarged nontender axillary lymph glands. The precordium bulged slightly. The heart was greatly enlarged downward and to the left, the left border of dullness lying in the midaxillary line. The apex impulse was forceful and easily visible in the seventh interspace. The first sound at the apex was slapping in quality and preceded by a mid- and late-diastolic rumble. There was also a short systolic murmur at the apex. Along the left sternal border a faint early blowing diastolic murmur was audible. The rhythm was totally irregular at a rate of 160 beats per minute. The blood pressure was 154 mm. mercury systolic and 20 diastolic. The liver was palpable 4 cm. below the costal margin in the nipple line. There were no rheumatic nodules and no cyanosis or edema.

The urine was normal on two occasions. The hemoglobin was 80 per cent (T), the red blood cell count was 5,220,000 and the white count was 21,430. The corrected sedimentation rate was 0.57 mm. per minute. The Hinton reaction was negative. The electrocardiogram showed auricular fibrillation with a ventricular rate varying from 120 to 180. The basal metabolic rate on six occasions, after his rapid pulse rate was controlled, ranged from —1 per cent to —19 per cent, three times less than —10 and three times greater than —10.

The accompanying chart (Fig. 164) shows his course while in the hospital, including temperature, apex and radial pulse rates, respirations, medications, sedimentation rate, and white blood cell counts. Digitalis was discontinued

on the second day because of nausea. It was not certain whether he had had too much digitalis or was simply nauseated from congestion in the gastrointestinal tract. On the morning of the third day after admission following the administration of 30 grains of quinidine sulphate in divided doses of 6 grains each in twenty-four hours for two days, the pulse rate dropped from 130 to 80 beats per minutes and the rhythm became fundamentally regular, with much subjective relief of symptoms. Thereafter, while in the hospital, the pulse rate ranged from 80 to 90, occasionally rising to 100 or slightly above. The slight discrepancy in apex and radial rates after the auricular fibrillation ceased was due to premature beats. On account of evidence of ac-

Fig. 164.—Case I.

tive rheumatic infection, which, no doubt, made the auricular fibrillation so refractory to treatment, he was kept quietly in bed and advised to remain in bed for several weeks on his return home. He was discharged, much improved, on a ration of 12 grains of digitalis and 12 grains of quinidine sulphate daily in divided doses of 3 grains each. His basal metabolic rate on one occasion after leaving the hospital was plus 30 per cent. This was checked with total calorimetry in mind as a possible therapeutic procedure.

He was last seen on September 6, 1935, five months after his discharge from the hospital. Following his discharge he remained quiet for several weeks and continued on a daily ration of digitalis, 12 grains, and quinidine sulphate

3 grains, four times a day, for nearly three months. He improved remarkably and was able to work almost every day through the summer as an announcer at an amusement park. The digitalis was omitted and the dosage of quinidine sulphate reduced to 6 grains daily, 3 grains in the morning and 3 grains at night.

Physical examination on September 6, 1935, showed his skin well tanned and his general condition good. The apex impulse of the heart was visible and palpable in the seventh intercostal space 12.5 cm. to the left of the mid-

Fig. 165.—Case I. A, February 28, 1935. Fully digitalized but before intensive quinidine therapy. Auricular fibrillation, ventricular rate 120–180, well-marked right axis deviation, and deeply inverted S-T segments in Leads II and III. B, March 3, 1935. After quinidine sulphate in divided doses of 6 grains each five times a day for two days (60 grains in all). Normal rhythm, rate 80, interrupted every third beat by an abnormal QRS complex, probably a late premature beat. Prolonged P-R interval (0.23 seconds), right axis deviation, and persistent digitalis effect upon the S-T segments. C, September 6, 1935. After a fairly active summer. No digitalis for several months. Quinidine sulphate, 3 grains, twice daily, morning and night. Normal rhythm, rate 100, slightly prolonged P-R interval (0.21 seconds), prominent P₂, low but upright T waves in the conventional leads (disappearance of digitalis effect), and right axis deviation.

sternal line. There were moderate aortic systolic and diastolic murmurs, a slight to moderate apical middiastolic murmur, and a loud apical systolic murmur. The blood pressure was 140 systolic and 60 diastolic. The lungs were clear, the liver was not enlarged, and there was no edema over the shins or ankles. He was advised to carry on quietly, using 3 grains quinidine, twice daily, or more often if necessary, and, if possible, to spend the winter in a milder climate.

Figure 165 shows serial electrocardiograms during and following the auricular fibrillation.

Discussion.—So long ago as 1749 quinine was reported by Senac to be helpful in the control of rebellious palpitation, but it was used very irregularly and by most internists not at all, until about fifteen years ago, when its isomer quinidine was introduced by Frey,¹ after he had learned of the accidental discovery (by a patient of Professor Wenckebach's) of the beneficial effect of quinine in controlling paroxysmal auricular fibrillation.

Fifteen years ago quinidine was tried out in a large number of unselected cases of auricular fibrillation. Frequently it restored normal rhythm, but there were many failures and a few disasters which resulted in considerable dissatisfaction or actual fear in the use of the drug.

During the past ten years, however, in carefully selected cases, quinidine sulphate has been found useful and, at times, even life saving, as in our Case I, recounted above, who undoubtedly would have gone on to extensive congestive failure and death had there been a persistence of the uncontrolled ventricular rate in his obstinate auricular fibrillation.

There are three indications for quinidine therapy. In the first place it may save lives by the restoration of normal rhythm in cases of auricular fibrillation or paroxysmal ventricular tachycardia in the presence of serious heart disease (including coronary thrombosis) when other measures have failed. Secondly, it may restore normal rhythm in cases of persistent auricular fibrillation who show little or no heart disease, especially when they are uncomfortable as a result of the palpitation caused by the arrhythmia. And thirdly, in rations it may prevent disturbances of rhythm, particularly paroxysms of auricular fibrillation and also sometimes paroxysmal tachycardia and premature beats.

For the control of auricular fibrillation or paroxysmal ventricular tachycardia a good method of quinidine treatment has, in our hands, been to administer 6 grains of quinidine sulphate every two hours for five doses on a given day following a test dose of 3 grains (to detect any unusual sensitivity to the drug). This program of 30 grains of quinidine sulphate divided into five doses over a period of eight hours usually suffices to restore normal rhythm, but if the abnormal rhythm persists the program can be extended cautiously to include

one to two more doses in two to four hours, or it may be repeated the next day. Patients receiving these large doses of quinidine sulphate should be in bed under close observation and preferably with electrocardiographic control (for example, an electrocardiogram should be taken before starting quinidine, before the third dose, and before the fifth dose). Mild toxic symptoms such as slight tinnitus are not important, but severe symptoms of cinchonism, excessive tachycardia (over 150 per minute), or intraventricular block by electrocardiogram demand the omission of the drug.

Finally in the prevention of arrhythmias, rations of 3 or rarely 6 grains of quinidine may be taken one to four times a day (even at three hour intervals) for periods of days or weeks. The effect of a single dose lasts about four hours. Therefore, it is important to prescribe quinidine an hour or so before some particular effort or episode which might excite an attack of tachycardia or fibrillation. Looseness of the bowels (sometimes a favorable laxative effect) or a little deafness occasionally results from the long continued use of quinidine sulphate and may require omission of the drug or reduction in the dosage.

SALYRGAN

Case II.—A. E. B., a seventy-one-year-old merchant, till June in good health, was admitted to the Baker Memorial Hospital in September, 1932. His first serious symptoms had appeared three months previously while driving his car home from a family dinner. At the onset he complained of indigestion. After several hours he vomited and later developed a feeling of pressure in his chest and difficulty in breathing. He preferred to sit upright by the open window. He coughed and raised blood-tinged sputum. Respiration was wheezing in character. He remained strictly in bed for several days following this episode and had spent the greater part of his time in bed thereafter, though he drove his car on two occasions. Approximately nine weeks after the onset of symptoms he was found in a stuporous condition, thought to be uremic coma, from which he recovered in a few days. Coincidentally edema of the legs appeared and breathing became increasingly more difficult up to the time he was seen by us, in spite of a fair amount of digitalis and diuretics by mouth.

Physical examination revealed an elderly man who apparently had lost weight but who showed extensive edema of the legs, genitalia, and trunk. Breathing was somewhat rapid and labored. The pupils reacted normally. The upper teeth were replaced by a denture. Many lower teeth were missing. The tongue and buccal mucous membrane were bright red and moist; the tongue was sore. The heart apex and left border of dullness were in the sixth intercostal space, 13 cm from the midsternal line and well outside the mid-clavicular line. The heart sounds were of poor quality, the rhythm was regular except for an occasional premature beat, the rate was 86 beats per minute,

and there were no murmurs. The blood pressure was 128 mm. mercury systolic and 98 diastolic. There was evidence of a considerable quantity of fluid in the right chest, and many moist râles were found in the left lower lung. The liver was enlarged, extending 6 cm. below the costal margin, and there was moderate ascites.

The urine on several occasions showed the slightest possible trace of albumin and several white and red blood cells; the specific gravity varied from 1.014 to 1.018. The nonprotein nitrogen of the blood was 34 mg. per cent. The hemoglobin was 75 per cent (T), the red blood count was 5,050,000, and the white count was 12,700. The differential count and smear were normal.

The electrocardiogram showed ventricular premature beats interrupting an otherwise normal rhythm, rate of 90, P-R interval prolonged, 0.22 second, slightly slurred Q-R-S waves, and low T waves.

The severe congestive failure was thought to be the result of long-standing hypertension and attendant coronary disease. The prognosis was considered quite grave and it seemed that even with the best treatment his anasarca could be but temporarily controlled.

The accompanying chart (Fig. 166) shows at a glance the extensive therapy he received while in the hospital, including venesection, thoracentesis, digitalis, the xanthine diuretic theocalcin, and the mercurial diuretic salyrgan. His response to treatment was far beyond expectations and as the hydrothorax and edema cleared he improved gradually. Near the end of his hospital stay he was able to be fairly active, walking about, without dyspnea and free of edema except for very slight pitting of both feet posteriorly.

Following his discharge from the hospital on December 14, 1932, after an eleven weeks' stay, he did fairly well at home under a quiet régime, a maintenance dose of digitalis, and salyrgan two or three times a month. A constant low grade of congestive failure persisted, however, and varied with the response to diuretics.

One year following the onset of his original symptoms he was admitted to the hospital again on account of increasing congestive failure, weakness, and mental confusion. At this time he was quite dyspneic, and the respirations were of the Cheyne-Stokes variety. The lips and tongue were cyanotic. The cervical and arm veins were engorged. The heart apex impulse and left border of dulness were 12 cm. to the left of the midsternal line in the sixth intercostal space. There was a slight gallop rhythm at the apex and marked slowing of the heart rate with audible auricular sounds during the periods of hyperpnea, probably the result of an increase in A-V block (shown to be present by electrocardiogram). The pulmonic second sound was slightly accentuated. There were no murmurs. The blood pressure was 130 systolic and 80 diastolic. There was a moderate amount of fluid in the right chest and in the abdomen. The liver was engorged and palpable, 6 cm. below the costal margin. There was edema over the flanks and of the ankles. The electrocardiogram showed an unusual ectopic auricular tachycardia at a rate of 170 with varying degrees of A-V block (2:1 and 4:1) and a ventricular rate ranging from 42 to 84, also low voltage and a rare ectopic ventricular beat. The urine on two occasions showed a very slight trace of albumin and a low specific gravity (1.002 to 1.010). The blood counts and hemoglobin were normal. The nonprotein nitrogen of the blood was 44 mg. per cent on admission and 32 mg. per cent one week after admission.

His treatment on this occasion, was, for the most part, as it had been previously (rest, digitalis, theocalcin, and salyrgan). His response was good to the extent that his edema cleared but he remained quite weak and mentally

progressive congestive failure and general debility after remaining in coma for two days. He survived longer than we had expected him to do when we first saw him.

Discussion.—Salyrgan or mersalyl, a preparation of mercury in solution for intravenous or intramuscular injection has proved a great boon in the last decade as a vigorous safe diuretic in the control of the intractable congestion due to heart failure or even other cause (such as chronic constrictive pericarditis, in preparation for operation). Its use is a refinement developed from the giving of mercury by mouth introduced many years ago for diuretic purposes and the accidental discovery by Saxl² in 1920 of the diuretic properties of mercury given intravenously to a syphilitic patient with edema. One of the original preparations novasural (merbaphen) was much less effective and more toxic. A newer preparation, mercupurin (novurit), has been introduced, which in a few patients is more effective than salyrgan and may be substituted for it in the same dosage. Mercupurin contains mercury and theophyllin which also acts as a diuretic.

Salyrgan by its favorable diuretic effect has prolonged lives in many cases of obstinate congestive heart failure and has at the same time made life more endurable. This was true in Case II, recounted above. It is best administered intravenously in a dosage of $1\frac{1}{2}$ to 2 cc. with or without salt solution, great care being taken to avoid the spilling of any of the drug into the tissues around the vein or subcutaneously. If there is a leak of any of the salyrgan subcutaneously considerable pain and tissue destruction with ulceration are likely to occur. Intramuscular injection is safe but sometimes uncomfortable. This method may be used at the outset or in case the veins become thrombosed.

Salyrgan may be given at intervals of a few days or a few weeks as needed. It often is as effective after six months as it is the first day, and it rarely causes toxic symptoms or evidences of renal irritation. The urine should be watched with the latter possibility in mind. The drug is best given early in the morning, for its diuretic effect is most vigorous during the first twelve hours and thus the sleep of the patient is not interfered with. In a few cases where the diuretic effect of salyrgan or mercupurin is unsatisfactory diuretic salts may be given

by mouth for a few days previous to the administration of the mercury to enhance the effect, for example, ammonium chloride 15 grains (1 Gm.) four times a day if tolerated.

Some patients have been given an extraordinary number of injections of salyrgan over periods of a year or two, up to 100 injections or more. Also remarkable diuretic effects are seen occasionally, as much as 6 or 8 liters of urine in twenty-four hours.

Finally, it is important to record the daily fluid intake and urinary output, and if possible to obtain the daily weight of patients receiving salyrgan.

PARAVERTEBRAL ALCOHOL INJECTION FOR ANGINA PECTORIS

Case III.—H. J., sixty-six years of age, formerly a professional weight lifter, was admitted to the Massachusetts General Hospital for the fifth time on April 29, 1935. His first admission had been ten years previously at which time he complained of typical attacks of angina pectoris of about one year's duration. He had also noticed at that time some dyspnea on effort, nocturnal dyspnea, and swelling of the feet. His past history was irrelevant except for an attack of "rheumatism" at the age of forty-three involving chiefly his ankles, and two eye operations, one for glaucoma, and the other for cataract. Physical examination on his first admission revealed an obese man with extensive arcus senilis in both eyes and fixation and irregularity of the pupil of the left eye from operative procedures. Many teeth were missing. Those remaining were dirty and carious. There was moderate pyorrhea alveolaris. The heart was enlarged to the left, the sounds were of poor quality, and there was a rough apical systolic murmur. The blood pressure was 110 mm. mercury systolic and 50 diastolic. There were a few moist râles at the left lung base. The liver was palpable, 3 cm. below the costal margin and slightly tender.

x-Ray examination of the heart in 1925 showed a well-marked increase in the total transverse diameter chiefly to the left, and a widened tortuous aorta. The electrocardiogram showed sino-auricular bradycardia, rate 48, and intraventricular block with left axis deviation. Examination of the blood was normal. The blood Wassermann reaction was negative. The nonprotein nitrogen of the blood was 35 mg. per 100 cc. of blood. The urine was normal on several occasions.

Following digitalis therapy and the removal of several abscessed teeth he showed moderate improvement and was discharged with a diagnosis of arteriosclerotic heart disease and angina pectoris. He was advised to continue with digitalis, $1\frac{1}{2}$ grains daily, and to take potassium iodide, 10 drops three times a day.

He moved his place of residence and was not seen again for six years. In September, 1931 he returned complaining of frequent attacks of angina pectoris even when at rest. He was very nervous and reacted severely to his attacks of pain which made them totally incapacitating. The pain, for the most part, radiated to the left shoulder and down the left arm, but occasionally to the right shoulder and arm. On account of the crippling nature of his attacks which did not respond to the usual medical measures, paravertebral alcohol

(95 per cent) injection was advised and carried out by Dr. J. C. White. The first, second, third, and fourth dorsal sympathetic ganglia on the left were injected. Except for pleural pain incident to the injection and intercostal neuralgia for several weeks following the injection there were no complications. He was discharged on the tenth postoperative day considerably improved, having had no substernal pain since the injection was made. The electrocardiogram at this time was essentially as previously described, the heart rate being 60.

Following the left-sided injection he had no further pain over the left precordium nor down the left arm. But as time went on he continued to have substernal oppression with radiation to the right side. This became quite as incapacitating as the pain which had previously radiated to the left side. Along with this were some symptoms and signs of myocardial weakness such as dyspnea on effort and at times a few râles at the lung bases, but never any gross evidence of congestive failure.

In May, 1934, nearly three years after the left-sided alcohol injection he was admitted to the Massachusetts General Hospital again. On account of the continued severity of his symptoms alcohol injection on the right side was considered. However, injection of the first five dorsal sympathetic roots with novocain alone was tried first. This resulted in almost complete relief of pain for a period of about ten weeks following injection and justified a subsequent alcohol injection of the first, second, and third, right dorsal roots which was done a year later (April, 1935). Since that time to the present (December, 1935) he has been much improved. No severe attacks of angina pectoris have occurred and he is able to keep relatively comfortable by using several nitroglycerin tablets daily to control the slight substernal discomfort which he experiences on effort.

Discussion.—Paravertebral alcohol injection for the relief of pain due to cardiac or aortic disease has become an established and useful method of treatment, particularly in cases of intractable angina pectoris and large aortic aneurysms. It has developed from the crude early attempts to relieve angina pectoris by cervical sympathectomy which was introduced by Jonnesco³ in 1916. The development of our knowledge of the anatomy and physiology of the cardiac nerves has resulted in great improvement in the operative attack on angina pectoris. It is now possible to resect the nerves responsible for carrying the pain of angina pectoris to the central nervous system, namely, the first four or five dorsal rami communicantes on either side. Cervical sympathectomy is clearly recognized now as largely ineffective. However, the operation of dorsal sympathectomy is a difficult one and less advisable in most patients with angina pectoris than the much simpler but somewhat less accurate therapeutic measure of paravertebral alcohol injection.

In 1925 Mandl⁴ introduced paravertebral novocain injec-

tion which gives temporary relief from angina pectoris. Swetlow,⁵ the following year, introduced paravertebral alcohol block of these same dorsal sympathetic rami communicantes. Since that time the technic of paravertebral alcohol injection for angina pectoris and for the pain of aortic aneurysm has been greatly developed by James C. White.⁶ In the last 20 cases treated in this way by White there has been no failure to obtain the desired effect.

The procedure is carried out under local anesthesia on the side in which most of the pain of the angina pectoris is located or to which it is referred. This is usually the left side. In occasional cases both sides have been treated in sequence at intervals of days, weeks, or months. Long needles are inserted paravertebrally, usually at the level of the first four dorsal nerve roots. Novocain is then injected and the determination is made forthwith of its effect on the sympathetic nerves (Horner's syndrome, dry warm hand, anesthesia over the left chest). If the proper effects result from the novocain, alcohol is then injected. For details of the procedure see White's recent monograph on the autonomic nervous system.⁶

Aside from the failure to reach the proper sites there may be a few minor hazards concerned, that is, irritation or penetration of the pleura, and intercostal neuritis. Successful cases have shown usually permanent relief from a large part of the pain or distress on the side injected. Usually there remains a warning sensation which keeps the patient's activity under control. This sensation is not pain but a feeling of something wrong.

The patients to be selected for this therapeutic measure are cases of obstinate angina pectoris who are miserable from the constant repetition of angina pectoris even when leading much restricted lives, who have not been helped by medical measures consisting chiefly of rest and vasodilating drugs, and who are not thought to be suitable cases for total thyroidectomy, and also a few cases with severe pain due to the pressure of large aortic aneurysms.

Paravertebral alcohol injection probably has no direct influence on the underlying disease process, namely, coronary atherosclerosis, nor on the duration of life, but it does make

life much more endurable in most patients and it may conceivably even add to the duration of life indirectly by reducing the reaction incident to angina pectoris itself. Very rarely the removal of the disagreeable symptom of angina pectoris has resulted in careless overactivity and the precipitation of a fatal heart attack.

TOTAL THYROIDECTOMY FOR ANGINA PECTORIS

Case IV.—W. G. R., a sixty-seven-year-old physician, was first seen by us on April 7, 1934. He had always been a vigorous worker and well and active except for appendicitis in childhood and a recurrence of this condition at the age of sixty-two, requiring appendectomy. A ventral hernia resulted. In 1922 and in 1928 respectively, each time when very tired, he had a cardiac arrhythmia, probably consisting of premature beats, which was relieved on both occasions by taking a vacation from his busy practice. His blood pressure was said to have been persistently low (90–100 systolic) for a number of years.

In 1932 he first noticed substernal oppression on walking fast after dinner. This symptom recurred infrequently and mildly thereafter whenever he hurried. In November, 1933 the trouble increased sharply in frequency and severity, coming on slight provocation. It was relieved by whisky, but more promptly by nitroglycerin. During February and March, 1934, the pain, which had previously always come on slight or moderate effort, had occurred on six occasions at night while at rest. He was bothered occasionally by palpitation, but there was no dyspnea. His recent treatment had consisted of rest, omission of tobacco, euphyllin, and nitrites when necessary. These measures were not sufficient to control his symptoms. He slept poorly and was upset considerably by the serious illness of a relative.

Physical examination in April, 1934, showed him to be well developed and of large build. He seemed tired and quite nervous. His breathing was normal. The skin was slightly pale. The pupils reacted normally to light and distance. There was no arcus senilis. The thyroid gland was not palpable. The teeth were all out and replaced by dentures. The tonsils were normal in appearance. There was no engorgement or abnormal pulsation of the neck vessels. The apex impulse of the heart was felt in the fifth interspace, 9 cm. from the midsternum in the midclavicular line. There was no abnormal dullness at the base or to the right of the sternum. The heart sounds were of good quality, the rhythm was normal, the rate was 60, and there were no murmurs. The artery walls were soft. The blood pressure was 112 mm. mercury systolic and 70 diastolic. The lungs were clear. The abdomen and extremities were normal.

On fluoroscopic examination the heart was found to be slightly enlarged and the aorta somewhat tortuous. The electrocardiogram showed normal rhythm, rate of 80 and upright T waves in the three classical leads.

A diagnosis of coronary heart disease with angina pectoris was made. Normal activity seemed limited to the extent of 75 per cent by his cardiac condition, and the prognosis was regarded as uncertain. He was advised to rest more completely, to limit his activity according to symptoms, to eat a light reducing diet, to take phenobarbital three times daily, and nitroglycerin when needed. Alcohol injection of the dorsal sympathetic nerves was considered for later use as a palliative procedure.

He improved somewhat on the above régime but not sufficiently to permit him reasonable activity or the resumption of his practice. In June, 1934, he returned for further observation. At this time he was still nervous and impatient to have something more radical done. There had been essentially no change in his physical condition from that previously recorded. The pulse was regular at a rate of 72, the heart showed only slight enlargement, the heart sounds were excellent, there was no edema, and the blood pressure was 125 systolic and 80 diastolic. The basal metabolic rate on three occasions was found to be -11, -15, and -13 per cent respectively.

With the improvement in symptoms the possibility of coronary thrombosis seemed less likely. Therefore, in spite of his age and a rather low metabolic rate, total thyroidectomy was done on June 19, 1934, with the hope of improving the coronary circulation sufficiently for his needs of light activity. He withstood the operation well and went home on the eighth postoperative day.

Two months following the operation he reported that he had had no angina pectoris and was feeling well. The basal metabolic rates at one and two months after operation were -31 and -37 per cent respectively. He looked well except for slight puffiness beneath the eyes. The heart sounds were good, and the blood pressure was 110 systolic and 70 diastolic. He had gained weight. The electrocardiogram showed no change except for slightly lower T waves. At this time he was permitted to resume light work and was given thyroid extract, $\frac{1}{4}$ grain daily.

His condition has remained satisfactory up to the present time (December, 1935), especially when compared to the relative invalidism he suffered before thyroidectomy was done. He is well except for some coldness of his extremities and a little substernal aching on much walking, or on smoking which he has resumed. He has varied the dose of thyroid extract from $\frac{1}{4}$ to 1 grain daily. At the higher dosages the metabolic rate is correspondingly higher and substernal oppression is more easily provoked. For more than a year now he has worked steadily in his office and has made unhurried home visits, except for three weeks vacation during the summer of 1935.

The total time elapsed since total thyroidectomy was done has been seventeen months.

Discussion.—In 1927 a patient with heart disease and supposed thyrotoxicosis had a subtotal thyroidectomy performed at the Peter Bent Brigham Hospital in Boston and was much improved insofar as the heart condition was concerned for a period after the operation. Histological examination of the thyroid gland of this patient showed no disease. This was the experience behind the idea of thyroidectomy for heart disease. But several years elapsed before this method of treatment was actually instituted by Blumgart and Levine. At first the results were disappointing, the beneficial effects lasting but a brief time. It was then realized that total thyroidectomy, and not subtotal, was essential for the sufficient permanent reduction of the basal metabolic rate and work

of the heart, whereby the heart might recover from its state of fatigue and failure or from its coronary insufficiency. With the help of their surgical associate, Dr. Berlin, Blumgart and Levine then carried out total ablation of the thyroid gland in a series of patients with obstinate angina pectoris or congestive heart failure.⁷ In some of these patients there was a striking measure of relief, in others slight benefit, and in still others it was evident that the operation had not been advisable.

Total thyroidectomy in the treatment of obstinate angina pectoris or of recurrent congestive failure has hardly passed through its preliminary experimental phase. Some years more are needed for a completely satisfactory evaluation, but there are, at least, occasional cases still alive today who have been unquestionably benefited. One such case is that recounted above.

The selection of cases for the operation is of prime importance. In the first place the patient should have the full benefit of extensive medical treatment over a period of at least several months before being offered this operative measure. On a number of occasions we have seen patients who had had unsatisfactory response to rest and medication during the course of a few weeks, but who gradually improved with striking degree in the course of the next few months from medical therapy alone. In the second place there are patients in whom the operation is contraindicated. These include cases who are seriously ill with intractable congestive failure or recent coronary thrombosis, or, indeed, angina pectoris decubitus of very high degree. Other contraindications are cardiovascular syphilis, very low metabolic rates (minus 15 or minus 20 per cent or less), very old age (over 70), and the presence of a considerable amount of renal or pulmonary disease. It is also to be distinctly understood that total thyroidectomy does not have any beneficial effect on hypertension or on psychoneurosis which may complicate heart disease and exaggerate its symptoms. This leaves a small group of patients who are suitable for this therapeutic measure, mostly middle aged persons with angina pectoris or congestive failure, completely or almost completely free from symptoms while at rest in bed, but in whom the symptoms recur when up and about.

Total thyroidectomy itself is a major operation demanding very careful preoperative preparation, skilled surgery by an experienced operator, and careful postoperative attention. However, thyroid surgery had developed to such a degree, including its application to seriously ill thyrotoxic cardiac patients, especially by Drs. Lahey and Hamilton, that the stage was already set for this new procedure of total thyroidectomy in the treatment of heart disease. Postoperatively the basal metabolic rate sinks in the course of a few months to a low level, and signs and symptoms of myxedema then begin. At such a time or just before it, say two months after operation, thyroid extract in small dosage, usually $\frac{1}{4}$ to $\frac{1}{2}$ grains of Armour's Extract daily, should be instituted to prevent the development of frank myxedema. Moderate hypothyroidism with a basal metabolic rate between minus 20 and minus 30 per cent is, in most cases, the desired effect. It is important for patients to be closely followed and impressed with the need of maintaining this state in which both cardiac symptoms and myxedema are held in abeyance. It seems almost certain that in some cases, at least, life can be not only considerably prolonged, but also made more comfortable by total thyroidectomy. As a radical therapeutic measure, however, it needs to be reserved as therapy of last resort and applied to perhaps 1 or 2 per cent of cases with angina pectoris or congestive failure.

CHRONIC CONSTRICTIVE PERICARDITIS

Case V.—B. K., a girl aged ten years, entered the hospital on October 13, 1931, with a history of having lived a semi-invalid life since the age of five and one-half years due to a markedly enlarged abdomen resulting from the presence of much ascitic fluid. When she was twenty months old she suffered from what was apparently an attack of acute pericarditis, and her abdomen became enlarged at that time. At the age of two and one-half years a laparotomy was performed and a gangrenous appendix was removed. No tubercles were seen on the peritoneum at the time of operation. A drain was inserted, and the patient made a good recovery. The fluid returned in about three weeks but following an abdominal tap one month later there was no recurrence of fluid for three years. At the age of five and one-half years the abdominal fluid returned, and six months later a Talma operation (omentopexy) was done. Abdominal fluid injected into a guinea-pig gave negative results. There was no improvement following this operation, and at the age of nine the patient entered a second hospital for further study. Her abdomen was tapped at that time, but not again after that until her entrance into the Massachusetts General Hospital in the fall of 1931 when 6240 cc. of straw-colored fluid with a specific gravity of 1.013 were removed.

Her mother had died of tuberculosis during the patient's infancy. Her father is living and well.

Physical examination showed a thin, somewhat pale, young girl with heart apparently normal in size and sounds and without murmurs, and with prominent jugular veins and a large protuberant, nontender abdomen, filled with fluid (Fig. 167). x-Ray examination showed the heart and great vessels somewhat displaced to the right and anchored to the diaphragm; no pulsation was evident at the right border of the heart and great vessel shadow; the right pleura was thickened.

The electrocardiogram showed normal rhythm, rate 100, with inverted T waves in Lead 2 (Fig. 169, A).

FIG 167 - Case V at the time of her disability. Her condition was unchanged for seven years (five to twelve years of age).

Advice was given at that time that the chest be explored surgically and the adhesions constricting the right auricle, right ventricle, and great veins be freed.

After an interval of two years this girl returned to the hospital in an unchanged condition with persistence of the enlargement of the abdomen. The serum protein measured 4.3 per cent. x-Ray and electrocardiographic findings were as before.

Pericardial resection was carried out on November 16, 1933, and a moderately thickened pericardium containing calcareous plaques was removed from over the right ventricle and right auricle by Dr. Churchill. The pericardial tissue that was removed showed fibrosis and calcification on examination. There was a stormy time for two days after the operation. Finally spon-

Fig. 168.—Case V one year and a half after operation. Her cure was completely effected within a few months of the pericardial resection.

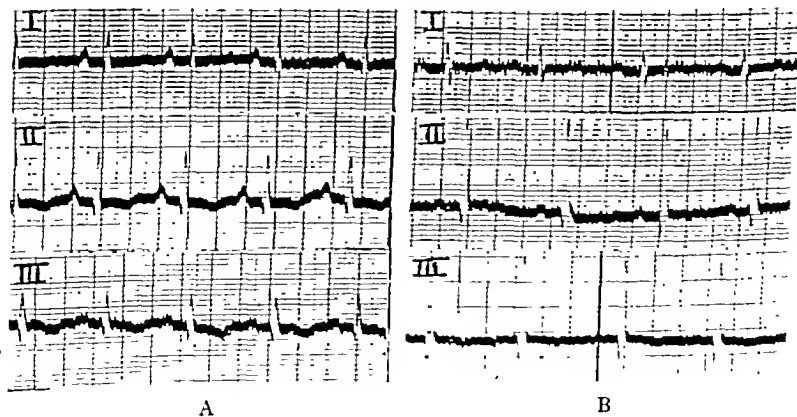

Fig. 169.—Case V.

taneous diuresis began and in the course of a few months the ascites completely disappeared. She has been in excellent health since, and looked well when she was last examined by us on May 16, 1935 (Fig. 168).

The electrocardiogram on May 16, 1935 showed normal rhythm at a heart rate of 80, with slightly upright T waves in Lead 1, flat T waves in Lead 2, and very slightly inverted T waves in Lead 3; this record differed from that taken before the operation in that the T waves were more normal and the voltage of the QRS waves was greater (Fig. 169, B).

Discussion.—Chronic constrictive pericarditis or Pick's disease, recognized by only a few medical observers over a period of several hundred years prior to the last decade, is at last amenable to treatment. Formerly a hopeless diseases treated by palliative measures to relieve dropsy, consisting chiefly of rest, restriction of fluid and salt intake, abdominal paracentesis and diuretics, it now yields to surgery in a considerable percentage of cases.

In 1895 Delorme of Paris tried to persuade the surgeons of his hospital to undertake to free the heart from its constricting pericardial adhesions. After three years of failure in his attempt to interest them, Delorme,⁸ in 1898, announced his ideas to the medical world in an open meeting in Paris, several years before Brauer⁹ offered his much less important plan of freeing the heart (rib resection and cutting of external adhesions). It is strange that Brauer's operation became much better known than the more vital pericardial resection advocated by Delorme. Finally, in 1913, Sauerbruch and Rehn independently carried out Delorme's suggestion. During the next ten years a few cases were operated upon in Germany, but it has been only in the last decade that pericardial resection has been firmly established as a cure for chronic constrictive pericarditis.

It is important in the first place to establish the diagnosis of chronic constrictive pericarditis. Following an infection which is often obscure but involves the pericardium and at times the pleurae and peritoneum (polyserositis), the pericardium becomes thickened, callous, constricted, and sometimes calcified. The cause of the original acute pericarditis is often unknown. In a few cases it is definitely tuberculous, in others it is associated with pneumonia and pleuritis; in a few it is septic in nature (when there is survival), but it seems never to be rheumatic. As noted by one of us in a recent

paper¹⁰ on chronic constrictive pericarditis, "The leading clues are the result of inflow stasis, namely, (1) the insidious onset of dropsy in a young person, (2) preponderant liver enlargement and ascites, (3) increased prominence of the jugular veins, (4) normal or relatively normal heart in the presence of dropsy without nephritis, and (5) low blood and pulse pressure and paradoxical pulse. Other important clues are (6) x-ray evidence (poor pulsation, calcification, chronic pleuritis), (7) electrocardiographic abnormalities (low voltage or coronary T waves in chronic disease in early youth), and (8) previous history of acute pericarditis or polyserositis." The three conditions most commonly confused with chronic constrictive pericarditis are rheumatic heart disease with mitral stenosis and congestive failure, primary cirrhosis of the liver, and polyserositis including instances of perihepatitis or frosted liver.

The operation itself, done under general anesthesia, preferably ether, is a difficult one and to be trusted only to a skilled thoracic surgeon. About an hour is needed for the approach to the chief operative field, namely, the pericardium itself. Three or four rib ends and costal cartilages, usually the fourth, fifth and sixth, and the left edge of the sternum are removed. The pleurae are carefully retracted, the pericardium incised and both parietal and visceral layers, usually adherent to each other and as thick as shoe leather, are carefully dissected off from the surface of the heart, most commonly from the right ventricle and right auricle. This procedure takes about another hour, and, if successful, the heart obviously expands during the course of the operation while it is being freed from the constricting pericardium, the pulse improves and the pulse pressure increases. Recovery may be rapid or slow following the operation. Sometimes a spontaneous diuresis develops during the course of the very first week postoperatively and in two or three weeks the congestion may entirely disappear, resulting in an early cure. In other cases progress is much slower and several months may elapse before there is marked improvement or cure. In a few cases operation may be unsuccessful and in another few it may cause an early fatality. In our own series of 12 cases of pericardial resection done at the Massachusetts General Hospital by one surgeon (Dr. E. D.

Churchill) there have been six cures, two other recent cases apparently on the way to a cure or high degree of improvement, and one other case more than 50 per cent improved. Thus, although this disease is rather rare, it is now of vital importance that it be recognized and its victims offered this new opportunity for cure. The history recounted above is one of our successful cases.

CLINIC OF DR. SOMA WEISS

FROM THE THORNDIKE MEMORIAL LABORATORY, SECOND AND
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY
HOSPITAL, AND THE DEPARTMENT OF MEDICINE, HARVARD
MEDICAL SCHOOL

RECENT ADVANCES IN THE TREATMENT OF ARTERIAL HYPERTENSION

SYNOPSIS

- I. General Consideration of Therapeutic Measures.
- II. Chemical Substances:
 - The nitrites.
 - The alkyl nitrates.
 - Bismuth subnitrate.
 - Tissue extracts.
 - Histamine.
 - Acetylcholine.
 - Acetyl- β -methylcholine.
 - Adenosine and adenylic acid.
 - Cucurbitacin.
 - Potassium thiocyanate.
 - Ovarian hormones.
- III Dietary Measures.
- IV Surgical Measures:
 - Procedures to influence the hormonal production of the glands of internal secretion.
 - Section of the splanchnic nerves.
 - Direct denervation of the suprarenal glands.
 - Suprenalectomy.
 - Operations for the purpose of influencing nerve impulses of the vasomotor system.
 - Denervation of the kidneys.
 - Section of the splanchnic nerves.
 - Spinal nerve root resections.
 - Combined surgical measures.
 - Critique of the surgical treatment of arterial hypertension.
- V Conclusion.
- VI Radiography

DEVIATIONS from the normal level of arterial pressure are often responsible for clinical symptoms and frequently lead to disturbances of bodily functions. While the prognosis in arterial hypotension is good as far as structural disturbances and longevity are concerned, the serious cardiac, neurologic, renal and other organic complications of chronic arterial hypertension are well recognized. In the prevention of these secondary vascular disturbances and "organ insufficiencies," adequate treatment of "uncomplicated" hypertension is essential. The following discussion will be restricted to an evaluation of attempts recently undertaken for the treatment of "uncomplicated" arterial hypertension.

I. GENERAL CONSIDERATION OF THERAPEUTIC MEASURES

Efforts to abolish arterial hypertension effectively have so far been uniformly characterized by failure. This is not surprising when one considers that in spite of significant evidence indicating that hypertension is the result of mechanisms of varied etiology, the details of these mechanisms are little understood.¹ As a result, no successful therapy directed against etiologic factors exists, nor can it be rationally devised at present. All one can attempt to do is to search for measures which tend to reestablish the normal level of the arterial pressure with the maintenance of adequate capillary blood flow through the tissues both at rest and during physiologic activities of the body. This latter consideration is particularly important, for although one can lower the blood pressure with relative ease in a number of ways, there is usually ultimate damage to the organs.

There are a number of facts now firmly established, the knowledge and proper evaluation of which are essential in the effective treatment of hypertension. In the majority of instances of arterial hypertension, in which both the systolic and the diastolic pressures are considerably elevated and the pulse pressure is usually high, the primary and most significant change consists in an increase in the "tonus" of the arteriolar as well as of the arterial walls.^{2, 3} The relative degree of involvement of the arteriolar and arterial systems, respectively, varies in different types of hypertension. The chief factor is usually the increased tonus of the arteriolar rather than of the

arterial system, which in turn causes a notable increase in the resistance of the vascular tree to the blood flow. The pressure within the capillaries, as judged from the behavior of the cutaneous capillaries and of the spinal fluid pressure, is usually but not necessarily, normal. Similarly, the systemic venous pressure and the pressure relations within the pulmonary circuit are, in the majority of uncomplicated cases, within the limits of normal. The circulating blood volume and the viscosity of the blood are also normal. Since the cardiac output, the stroke volume of the heart, and the maximal and mean velocities of the circulation are likewise normal, it follows that the mean supply of blood to the tissues is the same in patients with hypertension as it is in normal subjects.^{3, 4, 5} These findings, now confirmed, clearly indicate also that the increase in arteriolar resistance is diffuse throughout the body. That such is actually the state of affairs in the skin and in the striated muscle tissues is shown by direct observations recently made in this laboratory.^{6, 7} That in some of the organs ischemia and hyperemia may exist simultaneously as a result of a relatively increased constriction or relaxation of the arterioles is possible, and from certain observations is even probable.⁸ This does not, however, alter the fundamental fact that in spite of change in the physical properties (changes in tonus) of the arterioles and of the arteries a remarkable homeostatic regulation exists in hypertension which results in an adequate and normal supply of blood to the tissues at rest and under physiologic stimuli. This homeostatic adjustment is accomplished by increased work on the part of the heart and by increased arterial and arteriolar pressure on the part of the circulation. It is important to reemphasize that the circulatory adjustments in hypertension are performed with good economy, and that *there is no overabundance of blood supply to the organs in hypertension*. Such considerations inevitably lead to the conclusion that *arterial hypertension is primarily a progressive obstructive disease of the arteriolar system and a progressive alteration of certain physical properties of the arterial system*. The elevations of the diastolic and systolic pressures are secondary manifestations, and they must be looked upon as compensatory adjustments for the maintenance of adequate capillary circulation in the tissues.

The exact *nature of the change* in the arterioles and arteries is unknown. At the present time all that we know is that the increase in "tonus" can be either reversible, or partially or completely fixed. It has been assumed from indirect clinical evidence that the source of the increased tonus, particularly in the early stage of hypertension, is increased efferent sympathetic nervous impulses in the vasomotor system. Actually, clinical experimental attempts to demonstrate such striking difference in the tonus of the autonomic nervous system in patients with arterial hypertension as compared with that in control subjects have thus far failed.^{7, 9} Practically all the increased vascular responses observed in hypertension, which have been claimed to result from increased sympathetic impulses, can be explained as due to increased irritability of the vessels themselves. Our knowledge is therefore in a paradoxical state; namely, in spite of the fact that we can demonstrate changes in the tonus of the arterioles and arteries, we cannot demonstrate the increased sympathetic impulses, nor can we identify circulating chemical substances leading to increased tonus.¹⁰

This consideration of the mechanism of arterial hypertension is helpful in defining those characteristics which therapeutic measures must possess in order to be beneficial in hypertension. An effective measure must obviously decrease arteriolar and arterial tonus and resistance without essentially disturbing other fundamental characteristics of the circulation, such as the cardiac output, the velocity of blood flow or the volume of circulating blood. The measure must maintain normal and adequate blood flow to the organs, particularly to the heart, brain and kidneys, at rest and in times of physiologic stress. The effect of the measure must be such that sudden drops in the blood pressure are avoided, and if possible the spontaneous fluctuations present in hypertension toned down. Establishment of a permanent lower level should occur gradually. The vasomotor responses essential to normal bodily functions should not be affected.

Let us ascertain whether the measures introduced fulfill the rationale of these requirements.

II. CHEMICAL SUBSTANCES

The Nitrites.—The vasodilator properties of this group of substances have been known for a long time. It is only in late years, however, that the rationale of their use in arterial hypertension and in angiospastic disorders has been examined critically. Recently it has even been claimed that minute amounts of nitrites are normal constituents of the human blood.¹¹ The nitrites act chiefly, if not entirely, on the peripheral vascular system and produce vasodilatation, probably as the result of direct action on the smooth muscles of the vessel walls. The site of their activity is chiefly the arterial side of the vascular bed. The depressor effect is greater on the systolic than on the diastolic pressure. The comparative stability of the diastolic pressure suggests that the dilator effect of the nitrites on the small arteries and arterioles is neither constant nor marked. As far as the cardiac output is concerned, it either remains normal or becomes reduced. Similarly, the kidney function remains unaltered or becomes reduced as the result of the changes in the cardiovascular system.¹² These changes suggest that in some respects the nitrites are suitable agents for reducing arterial pressure. Their greatest drawback is their fleeting action. Moreover, in effective doses they may temporarily impair kidney function, and with the patient in the erect position they may cause increased strain on the circulation and at times fainting. The effects of sodium nitrite last but one or two hours, and some of the related compounds, such as amyl nitrite, have an action of much shorter duration, which can be measured in terms of minutes. Recently attempts have been made to use compounds that are absorbed slowly from the gastro-intestinal canal, such as bis-muth subnitrite, in order to insure a longer persistence of action. So far, however, such efforts have not proved successful. The short duration of action of the nitrites results in a constant and abrupt fluctuation of the arterial pressure, which in turn precipitates symptoms, and therefore their continued use may even become dangerous, particularly in patients with arterio-sclerotic changes. In view of these considerations, the main use of the nitrites is in acute vasospastic states, such as occur in vascular crises.

The Alkyl Nitrates.—The principal representatives of

this group, glycerol trinitrate, erythrol tetranitrate and mannitol hexanitrate, can induce marked reduction in the arterial tonus, particularly if the latter is increased. The duration of effect of this group of substances is again relatively short, though erythrol tetranitrate may lower the blood pressure for from two to three hours, and mannitol hexanitrate for as long as four or five hours. As far as the maximum depression of the blood pressure is concerned, 1 mg. ($\frac{1}{60}$ grain) of glycerol trinitrate is equivalent to about 30 mg. ($\frac{1}{2}$ grain) of erythrol tetranitrate or to 60 mg. (1 grain) of mannitol hexanitrate by mouth. It takes from twenty to thirty minutes for the last two substances to exert their action after oral administration.

For the same reasons as apply to the nitrites, the routine use of alkyl nitrates in arterial hypertension is not feasible; furthermore they are too expensive. Their main indication is in acute vasopastic states, such as occur in vascular crises and in angina pectoris.

Bismuth Subnitrate.—The beneficial effect of this substance has been reported by Stieglitz.¹³ It has been claimed that mild relaxation of the arterial system follows the oral administration of doses of 0.6 Gm. (10 grains) three times daily. Since this salt is relatively insoluble, there is a continuous liberation of minute amounts of nitrate within the intestines. It is claimed that under the influence of the colon bacillus the liberated nitrate ions are reduced to nitrites. Stieglitz and Palmer offered evidence to show that following the administration of bismuth subnitrate the nitrite concentration of the blood increases.¹⁴ Such medication serves a double purpose, according to Stieglitz. It reduces the arterial pressure and relaxes the arterioles, thereby breaking "the vicious circle of arteriolar fatigue." According to the experience of Stieglitz, a demonstrable reduction in the arterial pressure occurred in 77 per cent of the patients.¹³ The maximal reduction may be reached only after weeks of using the drug. Since the medication is certainly harmless and at the same time is inexpensive, it deserves trial as a symptomatic remedy, although in routine clinical use one has difficulty in seeing its benefit. Several reports in the literature also deny its therapeutic value.

Tissue Extracts.—During the past few years renewed claims have been made that extracts of muscle, liver, heart,

pancreas, brain, kidney and spleen exert a beneficial influence in arterial hypertension and in other vascular disorders, particularly angina pectoris. Such extracts, under the trade names of "myol," "lacarnol," "myoston," "padutin," "hormon kardiol" and others, are extensively used in Europe and America. That tissue extracts can reduce the arterial pressure in experimental animals has been known for a long time. The active factors were thought to be vasodilator substances. The recent claim, however, is that the alleged beneficial effect of these substances depends on circulatory hormones and only secondarily on vasodilator substances. For the existence and the nature of such circulatory hormones little and rather poor evidence is found in the literature; it is questionable, therefore, whether any greater benefit can be attributed to these preparations than to the combination of vasodilator substances contained in tissue extracts. These substances include histamine, choline and adenosine or adenylic acid and their derivatives. The cardiovascular effect of other substances present in tissues is negligible. Until we attain greater understanding of the effect of these substances on the vascular system, the clinical application of tissue extracts containing variable concentrations of vasodilator substances must be considered as empirical and unsettled.

Histamine is often considered as a potent vasodilator substance, and in certain species of animals, under experimental conditions, such is the case. It has been shown, however, that normal subjects given an intravenous infusion of histamine up to toxic doses continuously for two hours fail to respond with an appreciable lowering of the arterial blood pressure.¹⁵ In some instances the diastolic pressure shows a tendency to fall, but in numerous instances it remains unaltered. As judged from the behavior of the hemodynamics and from the vascular responses, arteriolar dilatation develops only in certain organs, and is associated with such changes in the heart and other organs as to make the therapeutic application of this or related substances as vasodilators questionable. It is of especial interest that when observations similar to those conducted on normal subjects were made on a group of patients with arterial hypertension, the response was similar in every respect to that observed in normal subjects. From the same concen-

tration of histamine the degree of elevation of the skin temperature was the same in normal subjects as in patients with arterial hypertension. This indicates that the degree of relaxation of the cutaneous arterioles was actually less in the hypertensive than in the normal subjects, but that the degree of increase in blood flow was the same in both groups.¹⁶ This constitutes additional evidence that in arterial hypertension the arteriolar responses to physiologic and other stimuli are such that the resulting blood flow is within the limits of normal.

These findings, together with its fleeting action and the fact that it is entirely ineffective even in massive oral doses, make histamine entirely unsuited for use in the treatment of arterial hypertension.

Acetylcholine.—The work of Dale and his associates¹⁷ has amply demonstrated that choline, a derivative of lecithin, and its esters represent the most potent vasodilator constituents of tissue extracts. Recently it has also been claimed that some of the choline compounds play an important rôle as chemical mediators of nerve impulses on cells with motor activities. It has also been proposed that choline acts as a regulator of intestinal peristalsis and tone. It is a remarkable pharmacologic fact that by the introduction of an acetyl radical the physiologic potency of choline in reducing arterial pressure increases one hundred thousand times, and such a minute amount as 1 cc. of a 1: 100,000,000 dilution of acetylcholine produces a fall in the blood pressure of the rabbit of 20 to 25 mm. Hg. It was natural, therefore, to expect that a substance with such biologic properties might be a suitable agent for the treatment of arterial hypertension. As a result of such claims by French clinicians, acetylcholine (under the trade name of "acecoline") came into use as a vasodilator.

The following consideration of the action of acetylcholine in man reveals at once that its therapeutic applicability as a vasodilator is limited. First of all, it has been demonstrated that man is relatively tolerant to this substance.¹⁸ After oral administration of even massive doses no systemic effects are noted. Even when as large a dose as 1 Gm. (15 grains) is infused evenly intravenously within a period of ten minutes, and mild toxic manifestations are precipitated, the arterial pressure either remains normal or is only slightly reduced. A

moderate degree of arteriolar dilatation develops, but circulatory adjustments apparently compensate for the dilatation in such a manner that the blood pressure does not change significantly. Furthermore, the effect is only transient, owing to the fact that acetylcholine is promptly destroyed within the blood stream. The effect of intramuscular administration of acetylcholine is unreliable and variable. In the few instances in which we have observed the effect of acetylcholine in patients with arterial hypertension we have found the response of the cardiovascular system similar in every respect to that in normal subjects.

These considerations, together with the expense, clearly demonstrate that acetylcholine is not a suitable substance for routine use in arterial hypertension. In certain acute vasospastic states, on the other hand, it may be useful when it is administered intravenously with proper understanding of its pharmacologic and toxicologic qualities.

Acetyl- β -Methylcholine.—This substance, like acetylcholine, produces vasodilatation and a certain type of parasympathetic stimulation.¹⁹ When given intravenously to anesthetized animals, the vasodilator effect of the two compounds is of the same order of magnitude, but the action of acetyl- β -methylcholine ("mecholin") is of longer duration owing, presumably, to its slower hydrolysis in the blood. Following subcutaneous injection, acetyl- β -methylcholine is more effective than acetylcholine. The general as well as the cardiovascular responses in normal human subjects following the continuous intravenous infusion of acetylcholine and acetyl- β -methylcholine are similar, but the latter substance is approximately two hundred times as potent as the former.²⁰ The duration of action of these compounds is very short. In man, mild systemic responses can be induced following oral administration of acetyl- β -methylcholine. These facts indicate that for parasympathetic stimulation and in acute vasospastic states acetyl- β -methylcholine offers advantages over acetylcholine. The effective subcutaneous or intramuscular dose varies from one individual to another, and may be from 5 to 30 mg. ($\frac{1}{12}$ to $\frac{1}{2}$ grain).

Adenosine and Adenylic Acid.—These and related compounds are, like histamine and choline, natural constituents of

the human body and active principles of organ extracts. Adenosine is formed with ease by the hydrolysis of nucleic acid. Adenosine and adenylic acid are practically identical in their pharmacologic effects, which depend on the ease with which they are deaminized in the body.²¹ They act primarily on the heart, and, to a lesser extent, as dilators, on the vessels, including the coronary arteries. Effective doses produce slowing of the heart and disturbances in the intracardiac conduction, leading to block. In tachycardias, including auricular fibrillation, they may induce slowing. In man, intravenous injection of 0.2 to 3 cc. of a watery solution causes sweating, a sensation of warmth, tremor, and restlessness associated at first with tachycardia and later with bradycardia.²² The T waves of the electrocardiogram may become flat, and delay in conduction may develop.

The evidence for the beneficial effect of these compounds in disease is meager. The combined effect of the cardiac slowing, disturbances of cardiac conduction, vasodilatation and fall in blood pressure which they produce is such that the function of the heart and the state of the circulation are usually not improved, and at times are even made worse. In view of this fact and also in view of the fact that their action is only transient, the therapeutic use of these compounds is undesirable.

The pharmacologic and therapeutic effects of histamine, choline, and adenosine and its related compounds cast *serious doubt on the claims as to the benefit of tissue extracts in hypertension* and in certain other vascular disorders. At best they produce only a fleeting effect, and when administered orally they must be practically inert.

Cucurbocitrin.—Extracts of watermelon seed contain glucosides and saponins, which, according to Barksdale, produce a lowering of the arterial pressure as a result of peripheral dilatation.²³ It is claimed that this depressor effect is also obtained after oral administration. No ill effects have been observed. This compound, under the name of "citrin," has so far not proved a particularly useful agent. No further report on its therapeutic use has appeared recently.

Potassium Thiocyanate.—Ever since Pauli's claim in 1903 that thiocyanate was effective in reducing high blood pressure, the use of this drug has been advocated from time to

time. Its toxic properties have not been sufficiently appreciated, however, in spite of the fact that they were emphasized by Claude Bernard in 1857. The therapeutic dose should not exceed 1 Gm. (15 grains) per day, and even after such a dose toxic reactions may occur. After larger doses, muscular weakness, psychosis, dermatitis, cardiac pain and fatalities occur. Impaired renal function apparently increases toxicity. Some persons show susceptibility to the drug. The margin of safety between the blood pressure reducing and the toxic doses is narrow. The detailed mechanism of its action has not been investigated as yet. As judged from recent reports, the indiscriminate use of thiocyanate is dangerous.

Ovarian Hormones.—It is claimed, especially by German writers, that certain extracts of the ovarian hormones, particularly follicular hormones, lower the pressure and alleviate the symptoms in hypertension. That progynon, administered orally in doses of 1800 units daily, is capable of abolishing the hot flashes of menopause is known. This is the more interesting because, in spite of the fact that in menopause there is underproduction of estrin and overproduction of prolan A, the hot flashes cannot be directly related to the low estrin content or to the high prolan A production.²⁴ We have pointed out before that the symptoms of uncomplicated menopause, of hypertension appearing during menopause, and of uncomplicated hypertension are essentially identical.²⁵ Hence estrin may well exert a beneficial effect on the symptoms of hypertension. Whether such therapy influences the level of the arterial pressure has not been established. In 2 cases followed by Albright such hypertension remained unchanged.²⁶

III. DIETARY MEASURES

In recent years the most important advance in the dietary treatment of high blood pressure consists in the correction of dietary restrictions and fads advocated in the past. There now exists adequate evidence that primary hypertension is not associated with metabolic disturbances, and that the kidney function remains good or fair in the majority of instances. In the Boston City Hospital about 10 per cent of the cases with nephrosclerosis die from uremia. It is doubtful whether in

this 10 per cent early protein or salt restriction would essentially have altered the outcome. Hence low protein and intensely restricted salt diets have been abandoned. In view of the chronicity of the condition, such diets often result in deficiency states and precipitate secondary complications. The only significant fact related to diet which we have learned is that in cases of overweight a balanced low caloric diet, which will result in weight reduction, will also result in effective and permanent lowering of the blood pressure. Reduced weight, in addition, lessens the work of the heart. Thyroid extract, dinitrophenol or other reducing agents should not be used, for they may precipitate cardiac disturbances. It is obvious that condiments and an excess of salt should be avoided. It is perhaps rational to encourage a moderately increased water intake, but no reliable evidence has yet been furnished that natural or artificial mineral waters have any specific beneficial effect. Alcohol in minute amounts is a natural compound of the body and burns with ease. Its excessive use is especially harmful to hypertensive patients; its moderate use, particularly in the form of beer or wine, is actually beneficial as a mild relaxer, sedative and vasodilator. In acute vasospastic states it has a distinctly beneficial effect.

IV. SURGICAL MEASURES

In recent years vigorous attempts have been made to influence hypertension permanently through surgical measures. In view of the fact that the primary disturbance in arterial hypertension consists in reversible alterations in the physical properties of the arteriolar and arterial systems, and in view also of the fact that during the past decade neurosurgery has made important contributions in the treatment of certain peripheral vascular disorders, it is natural that such attempts should be made. On the other hand, it is particularly important that physicians should realize that the value of these measures is far from being established, and that they must be considered as empirical rather than as based on a rational knowledge of the etiology or, for that matter, even of the mechanism of hypertension.

The surgical measures which have been advocated may be divided into two main groups: (a) procedures devised to

influence the hormonal production of the glands of internal secretion, and (b) operations for the purpose of influencing nerve impulses of the vasomotor system.

PROCEDURES TO INFLUENCE THE HORMONAL PRODUCTION OF THE GLANDS OF INTERNAL SECRETION

Of the glands of internal secretion the pituitary, thyroid, adrenal and ovarian glands have been regarded as being responsible for the development of arterial hypertension. There is little basis for such claims, the most tangible evidence so far presented being the claim of Cushing²⁷ and others that *basophilic adenoma or basophilic infiltration of the anterior lobe of the pituitary* is associated with hypertension. The significance of basophilic infiltration of pituitary cells in relation to hypertension, however, is not settled, and we lack adequate controls. Thus recently Ahlström²⁸ has denied the existence of a direct relationship between basophilic infiltration and hypertension. Patients with hypertension frequently have no basophilic infiltration and, contrariwise, patients with basophilic infiltration may have normal blood pressure. He quotes Spark, who also failed to find a relationship between basophilism and hypertension.* So far, perhaps fortunately, nobody has devised surgical procedures to influence pituitary secretion as a measure in the treatment of arterial hypertension. Reports on attempts to irradiate the pituitary gland with x-rays are beginning to appear in the literature, but no convincing evidence as to the benefit of this procedure has yet been presented. Moreover, it is not clear whether such a measure is harmless.

There are two arguments that may be brought forward in favor of the *suprarenal origin of hypertension*: (1) that an overproduction of adrenalin is responsible for hypertension; (2) that an unusual sensitivity to a normal secretion of the gland exists. With the exception of the rare cases of medullary tumors of the adrenal associated with the paroxysmal type of hypertension, there is no direct or indirect evidence

* Since this paper was sent in for publication a report by Scriba has appeared (Die basophilen Zellen des Hypophysenhinterlappens und ihre Beziehungen zum Hochdruck und zur Eklampsie, *Klin. Wchnschr.*, 14: 1589, 1935). He also failed to find a causal relationship between basophilic infiltration and hypertension.

supporting the contention that circulating adrenalin is responsible for arterial hypertension. *The hemodynamics and behavior of the patient with arterial hypertension differ essentially from those observed in animals or in man during experimentally induced hyperadrenalism.* We have observed that histamine, which in several respects is an antagonist of adrenalin, exerts no influence on any type of hypertension. It is also significant in this connection that complete ablation of the thyroid gland apparently fails to influence the course of arterial hypertension. It is well known that thyroid secretion exerts a sensitizing effect on the action of adrenalin on the cardiovascular system. One would therefore expect that if hyperadrenalinemia, or increased sensitivity of the blood vessels to normal adrenalinemia existed, a change in the hypertension would follow the complete elimination of thyroid secretion.

In spite of these basic considerations, surgical attempts to influence suprarenal secretion have been made and beneficial results have been claimed. Three types of operation have been performed for this purpose: (1) unilateral or bilateral section of the splanchnic nerves; (2) direct denervation of the suprarenal glands; (3) various degrees of suprarenalectomy.

Section of the Splanchnic Nerves.—This operation was suggested as a therapeutic procedure in arterial hypertension by Danielopolu as early as 1923. In 1923 Pende²⁰ advised section of the left splanchnic nerves for the production of vasodilatation within a large abdominal area and for the inhibition of adrenal secretion. Pieri³⁰ in 1932 resected both splanchnic nerves in 5 cases of essential hypertension. Craig and Brown³¹ performed unilateral or bilateral resection of the splanchnic nerves and removed the first lumbar ganglion in 5 cases. They claimed that the operation is relatively safe. In only one of their patients was the subjective and objective improvement striking; in two the only change was the reduction in the pressure reactions to cold, and in the remaining two with early renal involvement and advanced organic changes in the arterioles no benefit was noted. Craig and Brown recognize the fact that removal of the sympathetic nerves does not materially alter the arterial pressure. They think that resections influence the "response" or vasopressor reactions in hypertension. Excessive reactions, it is claimed, cause abnormal

wear and tear on the vascular system. The purpose of the surgical measure is to block or modify these excessive responses before the onset of organic or irreversible lesions. Patients with the "spastic" or "vasomotor" types of hypertension are therefore the most suitable subjects for operation. In a recent communication to me³² Dr. Brown states that in his opinion, however, the results with subdiaphragmatic bilateral resection are "rather equivocal and not at all dramatic."

Peet³³ has performed bilateral splanchnic nerve section on over 60 patients, all of whom had a systolic blood pressure of 200 or over. His intention was (1) to diminish peripheral blood volume through splanchnic dilatation; (2) to diminish adrenal secretion, and (3) to abolish abnormal vasoconstrictor effects of kidney origin, provided sclerotic changes in the kidney were not too advanced. He also claims that it is conceivable that after removing the elements of spasm and the strain of hypertension, the vessels "might" return to normal. He believes that in 6 cases in which complete relief was obtained such a process accounted for the return of normal kidney function. He confesses that no criterion as to the operability has yet been found. Marked fundus changes and evidence of greatly impaired kidney function are not contraindications. In a recent personal communication Dr. Peet³⁴ states: "We are continuing to do splanchnic operations for hypertension and believe our results are, on the whole, superior to those obtained by any other of the various surgical procedures. The operation, as developed by us, consists of a superdiaphragmatic approach with resection of the greater and lesser splanchnic nerves and of the lower dorsal sympathetic chain, including 10, 11 and 12 dorsal ganglions. We have always performed the operation bilaterally. Sixty-two per cent of our patients who have gone at least four months after operation showed very definite improvement and a considerably higher percentage have had relief of symptoms. About 15 per cent are cured so far as any evidence of hypertension is concerned. These have all gone at least six months and have maintained normal blood pressure while actively engaged in their former occupations, and have had a complete disappearance of all eye and kidney findings. We have operated over 100 patients. The longest has been followed two years and is maintaining a nor-

mal pressure, normal vision, and normal kidney findings. Before operation he had a blood pressure ranging from 240 to 280 over 180 diastolic. He had choked discs and markedly impaired renal function."

Direct Denervation of the Suprarenal Glands.—This procedure was devised by Crile³⁵ for the relief of symptoms of neurocirculatory asthenia. Others³⁶ have observed indifferent results following the same operation. It is said that this technic is now practiced in some clinics for the relief of hypertension. Recently, Rogoff* has reported the occurrence of "Addison's Disease Following Adrenal Denervation in a Case of Diabetes Mellitus." He warns: "The course and outcome in this case strongly support the contention, repeatedly made by me since 1918, that surgical intervention with the adrenals for various conditions (Raynaud's disease, spontaneous gangrene, hypertension, epilepsy, gastric ulcer, thyroid disease, diabetes, and the like) is to be deprecated. The very fact that it is alleged to be of benefit in so great a variety of diseases ought to render the practice suspect."

Suprarenalectomy.—The experiences of Galatà,³⁷ of Monier-Vinard, and Desmarest³⁸ and of Pieri³⁹ with unilateral suprarenalectomy do not reveal any benefit following operation. The blood pressure became lowered for only a short period, and obviously this was the result of surgical trauma. The surgical removal of pheochrome tumors of the suprarenal, on the other hand, has resulted in marked benefit to the patient.³⁹

DeCourcy, DeCourcy and Thuss,³⁶ believing "that the most rational method of treatment of essential hypertension is the surgical excision of sufficient amounts of glandular tissue to relieve the excessive functioning of the gland itself," removed about two-thirds of each suprarenal gland, including both medulla and cortex. They claim benefit in some of the patients as far as symptoms and lowering of the blood pressure are concerned. From their presentation it is difficult to judge the extent of the control observations.

* Jour. Amer. Med. Assoc., 106: 279, 1936.

OPERATIONS FOR THE PURPOSE OF INFLUENCING NERVE IMPULSES OF
THE VASOMOTOR SYSTEM

These procedures may be grouped into the following main groups: (1) surgical denervation of the kidneys; (2) splanchnic resections; (3) anterior spinal nerve root resections; (4) combination of these procedures.

Denervation of the Kidneys.—This procedure was carried out recently by Page and Heuer^{40, 41} both in patients suffering from severe essential hypertension and in patients with chronic nephritis. Heuer freed the renal vessels and after visualizing the sympathetic nerves, removed the nerves from both the ventral and the dorsal aspects of the vessels. In the one patient suffering from severe essential hypertension, the operation failed to alter the level of the pressure or to improve the function of the kidney. In patients with nephritis the blood pressure was lowered for a few weeks after operation, but in all except 1 case it then regained its original level. The urea function of the kidney remained essentially unchanged; two of the patients exhibited increased concentrating power.

Section of the Splanchnic Nerves.—This procedure has already been discussed in connection with denervation of the adrenals (p. 1356).

Spinal Nerve Root Resections.—This operation, proposed by Adson and Brown,⁴² consists in sectioning the anterior and probably also the posterior nerve roots from the sixth thoracic to the second lumbar segment. Even with such an extensive influence on vasomotor control and on intra-abdominal pressure, the result was not striking. Page and Heuer⁴³ report that following this type of operation in a young girl the arterial pressure returned to normal for seven months. Dr. Brown³² at present believes that in the malignant forms of hypertension the procedure has no influence on the course of the disease, but that in benign hypertension good results have been observed as late as five years after operation.

It is important to remember that in male subjects bilateral complete lumbar sympathectomy will induce sterilization. The patient will be able to perform the sexual act, with orgasm, but without ejaculation.

Combined Surgical Measures.—Finally, attempts are being made to investigate the effect of various combinations of the methods described above. The possible value of such a procedure can be surmised from the foregoing discussion.

CRITIQUE OF THE SURGICAL TREATMENT OF ARTERIAL HYPERTENSION

The following points have been, or may be, proposed in favor of the surgical treatment of primary (essential) hypertension: (1) there is an increased secretion of adrenalin which is responsible for hypertension. (2) Primary hypertension develops secondarily from a primary pathology in the kidney and is precipitated through afferent nervous impulses from the kidney. (3) There is a hyperactive vasomotor center in hypertensive patients with resulting increased motor nerve impulses and exaggerated pressor responses. (4) Even if there exists no increased vasomotor tonus in hypertension, an induced reduction of the normal tonus is desirable in view of the fact that the vascular system is hypersensitive to normal nervous and chemical stimuli. (5) Elevation of the arterial pressure produces wear and tear on the arterial and arteriolar systems; hence reduction of the arterial pressure *per se* is a beneficial procedure.

The following points bearing on these proposals must, however, be considered: (1) as far as cases of essential and of nephritic hypertension are concerned, there is no evidence that increased secretion of adrenalin is present. (2) Similarly, there is no evidence that essential hypertension is of renal origin, and surgical denervation actually fails to influence the state of essential hypertension. (3) There is inadequate evidence up to the present time to suggest that the efferent vasomotor impulses exert a greater constrictor effect in hypertensive than in normal subjects. Recent experimental evidence indicates that the vasomotor tone is not increased above normal in hypertension.⁷ (4) If the normal vasomotor tonus could be diminished diffusely in all organs without influencing deleteriously the essential physiologic responses, this would be beneficial. Thus far, however, this has not been accomplished. The decrease of vasomotor impulses within one region of the body, on the other hand, may well have a deleterious effect on the function of other organs in which the constricted state

of the arterioles persists, and in which now, as a result of the decreased blood pressure, a *suboptimal* blood flow will exist. (5) The studies of Cannon and his associates^{44, 45, 46} have demonstrated that the blood pressure responses of animals following various types of sections of the spinal sympathetic and splanchnic nerves are not uniform, and that they vary in different species of animals. Even after complete exclusion of sympathetic control of the blood vessels the blood pressure, after a postoperative drop, returns to approximately normal level. (6) While it is true that elevated arterial pressure represents wear and tear, it is equally true that persistent elevation of the capillary pressure may represent even greater wear and tear on these delicate vessels. It should therefore be appreciated that if one induces splanchnic arteriolar dilatation through nerve section, marked capillary hypertension will be precipitated. Thus we have shown that the local dilatation of an arteriole with histamine will elevate the normal capillary pressure in hypertension of 12 to 108 mm. Hg.⁶ It is questionable whether the benefit of the moderate drop in the systemic arterial pressure, claimed to result from the denervation, can outweigh the possible damage to the visceral organs, which will have to function under active hyperemia and under increased capillary pressure.

Granted that all the foregoing objections, based on experimental and clinical studies, can be obviated, there still remain the following fundamental facts enumerated earlier in this discussion, namely: (1) *arterial hypertension is primarily a progressive obstructive disease of the arteriolar system over the entire body*; (2) *the blood flow in the tissues in hypertension is practically always optimal or already suboptimal*; (3) *the elevation of the arterial pressure is a homeostatic adaptation on the part of the body for the purpose of maintaining optimal blood flow to the tissues at rest and under physiologic stress*. Suppose one effectively lowers the arterial pressure through splanchnic vasodilatation, one certainly cannot claim to influence the progress of the arteriolar constriction in the brain, heart, muscles and other organs. May not these patients ultimately predispose to cerebral and coronary thrombosis? From what we know regarding the compensatory capacity of the peripheral circulation in heart disease,⁴⁷ there

may be increased utilization of oxygen for a while and the symptoms may be masked, but the limit of peripheral circulatory adaptation will be reached. Thus, complications, which may be expected, will not become evident within from six to twelve months, the average period of observation in the majority of papers published.

The alleged symptomatic improvement of some patients does not necessarily justify such severe and far-reaching surgical interference as is advocated by many. One may lower the blood pressure and may abolish symptoms, but at the same time may also shorten the life of the patient, who otherwise might have lived for years in fair health. I do not wish to imply that it can be stated definitely that the surgical procedures advocated in recent years are dangerous or indifferent in their results. The conclusion seems justified, however, that adequate evidence as to whether the benefit of surgical measures outweighs their possible harmful effect has not been presented as yet. It is also obvious that some of these measures have been proposed either on false or on unproved premises or without proper appreciation of the clinical nature of hypertension, a condition which shows marked and irregular fluctuations in its course, and in which spontaneous and even permanent lowering of the arterial pressure is not a rare occurrence.

Surgery of the sympathetic nervous system has introduced some significant therapeutic measures, but it has also demonstrated numerous failures, so far as practical measures are concerned. For the practitioner, who primarily cares for the patient, this is important to appreciate. Investigation has to progress through intelligent and justified trial and error. It is wise, however, that physicians should accept therapeutic claims and particularly new surgical procedures only after proper evaluation of the problem and when there is strong supporting evidence. In case of arterial hypertension the presentation of such therapeutic proof is at best difficult. For the present, therefore, it seems advisable to leave the surgical treatment of arterial hypertension in the hands of those surgeons who believe that they can answer the problems raised in this discussion and who can eventually present adequate proof that there is lasting benefit to their patients.

V. CONCLUSIONS

Whereas some of the drugs described are effective in the relief of symptoms in hypertension and of vascular crises or other vasospastic states, an analysis of the evidence presented justifies the conclusion that the majority of them do not fulfill the therapeutic requisites outlined, and that their routine use in hypertension is therefore not advisable.

The value of the surgical procedures practiced recently for the relief of hypertension cannot be considered as established. Several important aspects of this problem have yet to be clarified.

Hence the rational management of hypertension consists in intelligent environmental management of the patient by means of rest periods, diet, psychotherapeutic guidance and sedation. The numerous complications of hypertension should receive specific consideration.

CLINIC OF DR. CHESTER S. KEEFER

FROM THE THORNDIKE MEMORIAL LABORATORY, SECOND AND
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY
HOSPITAL AND THE DEPARTMENT OF MEDICINE, HARVARD
MEDICAL SCHOOL

THE TREATMENT OF GONOCOCCAL ARTHRITIS, RHEUMATOID ARTHRITIS, AND GOUT

THE current medical literature contains numerous papers concerning the treatment of arthritis. Indeed, it is often difficult to evaluate many of the remedies suggested, since the type of joint disorder is not defined and the natural history of the disease is not taken into account when summarizing the results. It is no exaggeration to say that the adequate treatment of any disease can be carried out only if its cause is known. In many cases of chronic arthritis, and especially the rheumatoid type, the cause remains in doubt so that it becomes necessary to manage the patient in the most practical way. The treatment of any chronic illness is of necessity schematic in type and it must be based upon a rational and conventional diagnosis. In dealing with chronic arthritis, the treatment has the following objectives: (1) the relief of discomforts; (2) safeguarding the patient from deformities and increasing the function of the injured joints; (3) prevention, if possible, of the progress of the disease.

At the outset, it should be remembered that many of the procedures advised by the physician will require readjustment of the individual to the limitation of his or her activity which they must be taught to recognize. This requires considerable thought, tact and sympathy upon the part of the physician, and the best results are frequently obtained by paying meticulous attention to details.

In the evaluation of treatment, one must not forget the natural history of the disease. The question is frequently

asked by physicians—what would be the natural course of events if no particular form of treatment were given? The answer to this question has never been given, since practically all patients with arthritis receive some form of treatment. It is known, however, from the study of large groups of cases, that a certain number of patients, usually around 80 per cent, improve temporarily at least, regardless of the type of therapy employed. In these individuals the disease is relapsing in nature and may continue for years. In others, the disease advances without remissions and in spite of all available treatment. It is well, then, to take these facts into consideration before attaching too much significance to one type of treatment as a method of choice to the exclusion of others.

At this time the treatment of gonococcal and rheumatoid arthritis and gout will be discussed in the light of present-day concepts of these maladies.

GONOCOCCAL ARTERITIS

As far as we know, gonococcal arthritis is a true metastatic synovitis, but the tendon sheaths and other tissue of the body may be involved at the same time. The course of the disease, once it is established, may vary tremendously, depending upon the severity of the infection, the joints involved, whether or not reinfection occurs before recovery takes place, and the mode of treatment employed. In any event, the illness may last several months, causing great economic loss and in not a few cases, permanent damage to the joints. In the cases in which permanent damage takes place, there is usually damage to the articular cartilages during the acute phase of the disease, whereas if the disease is confined to the synovia the end-results may be better insofar as function is concerned. The treatment is carried out along the following lines:

1. Treatment of the primary focus.
2. Absolute rest of the joints during the acute phase.
3. Aspiration or irrigation of joints.
4. The use of fever therapy.
5. General upbuilding treatment.
6. Prevention of deformities.

When the knee or other large joints are involved in

gonococcal arthritis, and aspiration of the synovial fluid reveals a leukocyte count above 40,000 per cubic millimeter, and there are micro-organisms present, we usually advise the irrigation of the joint through a small incision in the capsule. It is especially important if the fluid is difficult to aspirate and contains large amounts of fibrin. After the joint has been washed out it is closed tightly, the knee is placed in traction and motion is started as soon as it is possible to do so without pain or discomfort. Our results with this method of treatment have been very satisfactory, with the immediate as well as the ultimate results.

The use of fever therapy either by the injection of typhoid vaccine or other methods has received an enthusiastic reception by many observers. It seems clear from the reported cases^{1, 2, 3} that hyperpyrexia seems to be most effective in the treatment of this type of arthritis. Five to seven treatments have been recommended and the temperature is elevated to 106° or 107° F. for five or six hours, every three to five days. The results of various authors have been summarized by Hench, Slocumb and Popp,¹ Schnabel and Fetter.² It appears that the best results are obtained in patients with acute gonococcal arthritis of short duration, and less striking results are obtained in the subacute or chronic types of cases. From the reports in the literature it would seem justifiable to use fever therapy in this type of arthritis more often in an attempt to learn more about the ultimate results of the cases treated in this way.

As one observes patients with gonococcal arthritis, it becomes apparent that many of them lose large amounts of weight and develop anemia, the muscles atrophy about the affected joints and the patients present the clinical picture which is so common in chronic infections. In our experience, blood transfusions for anemia and a liberal intake of food is highly desirable in such cases. The general upbuilding treatment is often of the highest importance.

When the above measures are followed, the results of treatment of gonococcal arthritis are usually satisfactory as far as the end-results are concerned. The course of the illness is often slow and even with the best of care, poor results are occasionally seen.

The convalescence is often difficult to manage and prolonged; efforts should be directed along the following lines:

1. Rebuilding muscle tone and strength about the affected joints.
2. The support of the arches of the feet, especially if the knees have been involved and the patient has been confined to bed for a long period of time.
3. Instructions regarding venereal disease prophylaxis.

RHEUMATOID ARTHRITIS

The cause of this type of arthritis is unknown. For this reason there is no adequate form of treatment for the condition. It is a malady characterized by remissions and relapses and there is no satisfactory evidence that any of the many remedies suggested are in themselves responsible for altering the course of the process. To be sure, many types of treatment are recommended, so that scarcely a year passes without the introduction of several new remedies. In the present state of our knowledge all one can hope to accomplish is to relieve the patient of as much discomfort as possible, to prevent the development of deformities when possible, and to give the patient the best possible opportunity of recovering from his disease through general upbuilding treatment and the correction of any abnormal functional disorders that may be present. It is highly important to discover, when possible, any factor that makes the patient worse. This can be done by questioning the patient and observing the course carefully. When these factors are discovered they should be eliminated.

Symptomatic Treatment.—The best form of symptomatic treatment is rest, especially rest in bed or absolute rest of the affected joints. Many patients maintain that the one thing that makes them worse is fatigue. The relief of pain can be accomplished by the use of drugs, the proper application of splints and supports to relieve muscle spasm, and the judicious use of local heat to the affected joints. Of the drugs which give most relief, the various salicylate compounds, and the atophan group are most effective. The latter group of drugs should be used with caution, since one occasionally encounters sensitivity to them.

Splints and support of affected joints should be applied early in order to relieve muscle spasm and prevent deformity. If deformity is inevitable, then the joint should be fixed in the most desirable position. These are problems that must be worked out in cooperation with the orthopedic surgeon.

General Upbuilding Treatment.—*Regulation of Activity.*—It is a good plan to keep the patient's joints at rest as long as there are any signs of inflammation present in the synovial membrane. The constant use of a joint which is the site of an inflammatory process only tends to increase the irritation and propagate the process. When the acute process subsides, exercise may be allowed within the limitations of the individual's ability to do work without fatigue or pain.

Diet.—One of the commonest questions that patients who have arthritis ask the physician is—what can I eat? Some physicians are of the opinion that altering the diet in various ways is of the highest importance in bringing about improvement; but aside from the cases in which there is a definite idiosyncrasy to certain foods there is little convincing evidence that high carbohydrate or other types of diet are responsible for the patient's symptoms. This question has been discussed at some length and in a critical fashion by Bauer, who concludes that "patients with rheumatoid arthritis should take a diet high in calories (unless they are overweight), high in vitamins and adequate in respect to calcium, phosphorus and iron." He points out that there is no convincing evidence that proves that a low carbohydrate diet is indicated in this disease, and that there is no proof that it is efficacious in curing the disease. With these conclusions I am in complete accord.

Removal of Foci of Infection.—The safest rule to follow in regard to foci of infection is to have them removed for their own sake rather than for the arthritis. By doing this, the patient is sometimes assisted in making a more rapid recovery. Before advising such procedures, definite evidence for the existence of infection should be present and the patient should be informed that such operations may be helpful but they may not necessarily be followed by improvement of the arthritis.

Miscellaneous Treatment.—*Anemia.*—When anemia of the hypochromic type is present it should be treated with iron, and in the cases in which it seems desirable to increase the hemoglobin or red blood cells more rapidly, whole blood transfusions may be given. The latter method has been used especially by Dawson and Boots.

Fever Therapy.—From time to time, various forms of fever therapy are used in the treatment of arthritis, including the artificial induction of fever with malaria, typhoid vaccine, diathermy, hot boxes, air-conditioned cabinets and so forth. Within the past year several excellent reviews of this subject have been presented by Hench, Slocumb and Popp, and Short and Bauer. As far as rheumatoid arthritis is concerned, there seems to be general agreement that the results obtained are of a temporary nature. Short and Bauer report that 80 per cent of their patients showed temporary improvement, but that this was maintained in only 20 per cent of individuals at the end of a two-year period or longer. The patients who seemed to respond most favorably were young individuals with arthritis of short duration, with little or no cartilage destruction, and with marked vasomotor changes who showed an increase in pulse pressure during treatment. They were of the opinion that the improvement in these patients was due to increasing the blood supply to the affected tissues. They concluded that this method of treatment was only occasionally justified and should not be used to the exclusion of general treatment.

From a review of the literature on the subject of fever therapy in rheumatoid arthritis, together with the results of personal observations, Hench, Slocumb and Popp came to the conclusion that the value of fever therapy could not be fully appraised at the present time. They expressed the opinion that a trial of fever therapy is justified in "selected" cases. Of 60 patients treated in this way, 70 per cent got little or no relief and the remaining 30 per cent received significant benefit.

A recent paper by Cecil, Freiss, Nicholls and Thomas⁴ relates their experience with malarial treatment of 13 cases of rheumatoid arthritis. All of their patients received temporary symptomatic improvement with disappearance of pain

and swelling after three or four malarial paroxysms. Within a period of six months after the termination of this treatment, 12 of the 13 patients had a return of their symptoms, but in four of these the general condition was thought to be better than before the treatment. The only patient who had not relapsed during the period of observation had had arthritis only four months before the treatment.

In brief, then, it appears that a small number of patients with rheumatoid arthritis are temporarily relieved following fever therapy. The experience so far would indicate that the improvement is lasting in only a few and that it is most striking in young individuals with arthritis of short duration, with marked vasomotor disturbances, but without cartilage destruction. It should be added that it is a procedure that must be carried out by a physician and a skilled nurse, since it is not an altogether harmless procedure. Hyperpyrexia and death have been reported.²

Vaccine Treatment.—This method of treating rheumatoid arthritis has been used widely for a number of years. In some instances vaccines have been employed to increase body temperature; in other cases, they have been injected in an attempt to increase the patient's immunity to certain strains of streptococci or to decrease his sensitivity to the products of these organisms. The strains of organisms used have been derived from the patient and attempts have been made to select the various strains on a basis of the patient's reaction to skin tests made with these organisms or by determining the presence of complement fixation bodies in the circulating blood. All of these procedures are based upon the assumption that rheumatoid arthritis is due to a streptococcal infection, and while there is some evidence to support such a conclusion, it is far from being settled. This question has been discussed in detail elsewhere and need not be repeated here.

The results of vaccine therapy are controversial. The recent observations of Wainwright⁵ indicate that 21 of 28 cases of rheumatoid arthritis showed improvement following intravenous injections of streptococcus vaccine prepared from the strain to which the patient was most sensitive. As objective evidence for the improvement, there was a relief of

pain, a reduction of soft tissue swelling and increased mobility of the joints, together with a uniform decrease in the skin sensitivity and an increase in the agglutinins in the blood of some patients.

Boots⁶ has recorded the results of his experience by saying that the value of vaccine therapy remains unproved. They have not been able to influence favorably the sedimentation rate of the erythrocytes, and other forms of treatment are followed by as great a clinical improvement as those on vaccine therapy. He expressed the opinion, however, that one can do no harm in trying it.

From the reports of vaccine therapy and from personal experience, it would seem that vaccine treatment should be tried in individuals in whom the arthritis has been preceded by an infection, and in whom one is able to demonstrate agglutinins and skin reactions to hemolytic streptococci. It will be generally admitted that it should not be used to the exclusion of general upbuilding treatment.

Sulphur Treatment.—Within recent years collodial sulphur has been used extensively in the treatment of arthritis. A recent paper by Rawls, Gruskin and Ressa⁷ records their results with this drug in a miscellaneous group of patients with arthritis, and summarizes the studies of others. They concluded that sulphur was a valuable agent in the treatment of arthritis, in spite of the fact that they did not feel that it was of much benefit in young people with rheumatoid arthritis. When improvement was noted, it occurred in older individuals with rheumatoid arthritis and in patients with "mixed arthritis and osteoarthritis." In these patients the cystine content of the fingernails was said to be low and "sulphur treatment is often beneficial."

One gains the impression from this paper as well as from others that the use of sulphur in the treatment of arthritis is purely empirical and that the evidence brought forth to support its use as a valuable agent in the treatment of arthritis is not very convincing, as far as the ultimate results are concerned.

Management of Convalescence from Acute Arthritis.
—This phase of the treatment of arthritis demands great attention since the individual's progress can be accelerated by

intelligent management. Fundamentally it consists in building up muscle tone and the structures supporting the affected joints by exercises and physiotherapeutic measures, and the use of various types of apparatus that may aid in the support of joints. The principles and methods that are used for the different joints have been outlined by Ober,⁸ and since the importance of these procedures are in following certain details, his paper should be consulted.

GOUT

The treatment of gout can be divided into three groups: (1) the acute attack; (2) the interval treatment; (3) chronic gout.

By general consent, it is agreed that the pain of acute gout is most severe, and may require large doses of such sedatives as opium to control it. The following procedures should be carried out: (1) Rest in bed. (2) Protection of the affected joints. (3) Forcing fluids to 3000 cc. a day. (4) Administration of purges in the form of wine of colchicum and tincture of rhubarb until a free diarrhea is obtained. (5) The use of atophan, alkalies and salicylates. (6) A diet that is high in protein and carbohydrate but low in fat and purine.⁹

Once the acute attack has subsided, it is well to advise the patient regarding factors that aid in preventing attacks. In many cases, the patients with gout know only too well what brings on their attacks; in others, they, as well as the physician, are unaware of the cause of an acute attack. Such conditions as dietary indiscretion, excessive fatigue or trauma to the various joints should be avoided. In addition, adequate care should be taken to see that these patients remain on a low purine, low fat diet with liberal amounts of protein in the form of milk, eggs, cheese, and an adequate amount of carbohydrate. Alkalies, salicylates and cincophen are also recommended in small doses and the fluid intake should be such as to give a dilute urine. Since these patients often have attacks following surgical operations, they should be prepared before operation by the treatment outlined above and by a low purine diet.

Chronic Gout.—The measures outlined above are used in the treatment of chronic gout, but in some cases in which

there are large deposits of urates in and about the joints, the treatment is unsatisfactory. I have recently observed a patient who has had attacks of gout for forty-six years, and at present he is completely incapacitated on account of the great deformity of his hands due to the deposits of urates, the destruction and ankylosis of some of the terminal phalanges. He informs me that only two things give him relief; one is colchicum and the other is the relief of tension in the affected joint that follows a puncture wound and the expression of urates. In these cases, treatment continues to be unsatisfactory and the nature of the disease needs further investigation.

CLINIC OF DR. J. H. MEANS

FROM THE THYROID CLINIC OF THE MASSACHUSETTS
GENERAL HOSPITAL

TREATMENT OF DISEASES OF THE THYROID

I HAVE been asked to give a clinic illustrating by means of cases some of the problems involved in the treatment of diseases of the thyroid—recent advances in the treatment of these diseases, in fact. I am not aware of any very recent advances in this field, at least, none that have got beyond what might be called an experimental stage. It is greatly to be hoped that we soon shall have a nonsurgical method of curing thyrotoxicosis and from the interrelationships of pituitary thyrotropic hormone and antihormones, in the sense of Collip, should the existence of these finally become well established, we have reason to hope that a nonsurgical treatment will presently emerge. Reports of remedies of this kind are to be found in the German literature, but their value has certainly not yet been established beyond all question. From a practical point of view we still find ourselves in the situation we have been in for some years, which is that subtotal thyroidectomy, during a period of full iodination is the best therapy we can advise for our patients suffering from toxic goiter.

Nor has anything very new recently emerged in the treatment of myxedema. In dried thyroid gland we have for years possessed an ideal treatment for the hypothyroid states and experience over a number of years has indicated to us that the wisest policy to follow is that of placing the patient on the minimum ration of dried thyroid, by mouth, which will rid him completely of all symptoms and signs of myxedema.

In the field of thyroid diseases not accompanied by change

in the function of the gland, which includes simple goiter, nontoxic nodular goiter, malignant goiter and inflammatory goiter, the principles of treatment consist in surgical removal when any of the following indications are present: (1) pressure; (2) suspicion of malignancy; or (3) unsightliness which troubles the patient; and occasionally irradiation in some form or other, either alone or in conjunction with surgery, in certain of the malignant cases.

It obviously is impossible, in the space allowed, to illustrate by cases all these different problems. Because the routine care of the various types of thyroid disease has been thoroughly discussed in previous clinics in this series as well as elsewhere,^{1, 2, 3, 4, 5, 6} I have decided that the best use to which to put the present clinic is that of illustrating how one works out the indications for treatment in some of the puzzling, complicated or atypical cases.

Let us begin with the case of Miss B. This patient, a lady of forty-three, consulted me first on March 25, 1935. She had had a subtotal thyroidectomy for exophthalmic goiter in a Middle Western city in February of 1933. In the autumn of 1931 she had had grippe and following this was in a rundown condition. Metabolic tests had been made showing a result of -7 and thyroid had been ordered. She had taken this for six weeks. According to her story it had had no noteworthy effect. In the summer of 1932 she had taken a trip abroad and had become very fatigued as a result. For this she again took thyroid intermittently. In the autumn of 1932 it was found that she was losing weight rapidly and having rapid heart action. She was seen in a private clinic in Boston and states that she was there told that she had no thyroid trouble. She continued to feel badly, however, and while visiting in the Middle Western city the diagnosis of exophthalmic goiter was made and operation performed as I have already stated.

Following her operation she was better in general but it took a very long time for her to get her strength back. She had been placed on Lugol's solution prior to the operation and had continued to take it ever since. During the year before I saw her, her eyes had become increasingly prominent. Her major symptom was fatigue. During the autumn of 1934 she had been so exhausted that she was almost bedridden for three months. She not infrequently had palpitation, but didn't sweat much. She had lost 3 or 4 pounds since the previous Christmas. Two weeks before she came to me she had a bout of diarrhea. She had had such bouts before operation but none since. Her catamenia were regular but scanty and brief. There was nothing in her past or family history that seemed to be significant.

My physical examination on March 25, 1935 showed a startled looking, middle-aged, thin woman who did not act in the slightest degree as though she had thyrotoxicosis. She had bilateral exophthalmos, more on the left than on the right, of moderate degree, bilateral lid lag, but no irritation of her corneae. She had no tremor and her hands were cold and dry. No thyroid

tissue could be palpated, no bruit could be heard in the neck, but a thrill could be felt in the region of the right lower pole of the thyroid. Her heart was rapid—rate 100, but not enlarged, rhythm was normal and there were no murmurs. Her blood pressure was 110/90. The remainder of the physical examination showed nothing of significance. She gave the impression of being a very lackadaisical, languid person. I may add that she was a lady of means and leisure, apparently without responsibility, whose chief interests in life were gardening, music and church work.

It was my very definite impression, when I first saw her, that she was not thyrotoxic, that she had no return of her Graves' disease and that her symptoms were upon a psychoneurotic basis—something which might be called, perhaps for want of a better name, effort syndrome. I was convinced that she had had exophthalmic goiter in the past because of the presence of the definite eye signs.

I obtained a metabolic rate determination which on April 2, 1935, showed levels of -5 and -10 for two consecutive periods. This seemed to square with the impression that she was not thyrotoxic. I ordered her to stop her iodine and then sat tight to see what would happen. What did happen was of great interest. On April 12 her metabolic rate had risen to $+17$ and on April 13 it was $+25$. Coincidentally with this her symptoms became greatly intensified. She became weak to the point of exhaustion and her pulse rose to a level of about 115; her skin became warm and sweaty. At this time a small amount of thyroid tissue was felt in the region of the isthmus.

The picture, therefore, had undergone an important change since the omission of iodine. There seemed little doubt at this time that she was thyrotoxic and that this thyrotoxicosis had supervened upon the omission of iodine. The natural further deduction was that she had been potentially thyrotoxic all along, probably ever since her operation, but that this thyrotoxicosis was a residual of rather small proportion which the ration of iodine was able to hold partially in abeyance. Dr. Arthur W. Allen was called in consultation and he agreed that the case was probably one of persistent and recurrent thyrotoxicosis and that further resection of thyroid tissue was indicated. A second operation was done on April 23, 1935. This operation was subtotal thyroidectomy upon the remaining tissue. A piece of thyroid about 5 cm. long, 2 cm. wide and $1\frac{1}{2}$ cm. thick was dissected out from the neighborhood of the right side of the trachea and the region of the isthmus.

The histologic picture of this removed tissue was that of definite parenchymatous hyperplasia with considerable colloid storage in places. This anatomic finding, therefore, confirmed the clinical impression of recurrent exophthalmic goiter.

The patient went through the operation very smoothly and on May 1, 1935 the metabolic rate was -11 , on May 6 it was -20 . At this time the patient was still taking iodine—Lugol's solution, 5 minims once daily. On that day she was discharged from the hospital and iodine was omitted.

I have seen her from time to time since and on the whole she has been considerably improved, although there are periods when her old feeling of weakness seems to return. On September 24, 1935, metabolic rate was -15 . I saw her on that date and my impression was that she was essentially well.

This case impresses me as being distinctly instructive. In the first place it was proved that persistent or recurrent thyrotoxicosis was present in spite of the fact that the patient

was running a metabolic rate below standard and presented symptoms which were by no means characteristic of thyrotoxicosis. Treatment necessarily hangs upon diagnosis. In this case the diagnosis was established by means of an iodine test carried out in a manner the reverse of that usually practiced; instead of noting the result of giving iodine, in this case, we noted the effect of omitting it. As soon as it was omitted the low grade thyrotoxicosis which the iodine had masked, manifested itself quite clearly.

On the first consideration of the case it would have seemed ridiculous to propose a second thyroidectomy for toxic goiter when there were no thoroughly characteristic symptoms, a slightly minus metabolic rate and very little thyroid tissue to be felt. None-the-less, it turned out that that was the correct treatment and the final result has proved this.

One may draw the general conclusion that before planning treatment in any thyroid case, the true level of functional activity must be determined and oftentimes this can only be done by giving or omitting iodine, or indeed doing first one and then the other.

Let us next consider the case of Mrs. B., a woman sixty-nine years old, who entered the hospital under my care on June 15, 1934, referred by Dr. Paul D. White. Dr. White had had this patient under observation since October, 1927, at which time he had made a diagnosis of irritable, slightly hypertensive heart with many ventricular premature beats. He had also observed at that time a slight enlargement of the thyroid with slight bruit. He had seen her at intervals since and she had always shown ventricular premature beats and some nervous symptoms. Nothing had happened, however, until a few weeks before entry when seeing her at her home Dr. White found she was losing weight rapidly and having tachycardia with many premature beats and a very full pulse pressure. He considered that thyrotoxicosis was very likely present.

Upon Mrs. B.'s entry to the hospital I did my best to decide at Dr. White's request (1) whether she was thyrotoxic, and (2) whether, if she were thyrotoxic, she was fit for operation. My physical examination at the time of entry disclosed a woman, not obviously hyperactive with none of the eye signs of exophthalmic goiter, with very slight tremor and with a thyroid isthmus and lateral lobes just barely palpable. Her heart was enlarged and fibrillating. No gross edema could be found anywhere. She was not orthopneic. The remainder of the physical examination was not highly informative.

She was put to bed and observed. The following metabolic rates were obtained: June 16, 1934, +33; June 19, +39; June 21, +35; June 23, +38; and June 26, +34. The maintenance of this elevated level in the absence of gross congestive heart failure was strong presumptive evidence of thyrotoxicosis. It was determined to observe the effect of giving iodine. After five days of

iodine, no fall whatever was noted in the metabolic rate level. The iodine was begun on June 22. Digitalis had been begun the day before. Under the influence of these two drugs the pulse rate slowly fell from a rate of about 120 to one under 100. There was no means of determining which drug was chiefly responsible.

I had been very dubious of the evidence of thyrotoxicosis at entry and recorded that opinion in the hospital record, however, after observing the level of metabolic rate I began to question the accuracy of this conclusion. The failure of her metabolism to drop in five days on iodine was inconclusive one way or the other. Further metabolic rate determinations should have been made, but since the tests distressed the patient considerably they were omitted.

Because of Dr. White's feeling that the heart condition was best explained by thyrotoxicosis, and because the surgeon, who saw the patient in consultation, believed that he could do a thyroidectomy successfully (he stated the risk was about five times the normal, however), and because the family were eager to leave no means of treatment unused that offered any hope of relief, I finally consented to operation on her thyroid. This was done on July 2, 1935. The operation itself went extremely smoothly. The patient returned to her room in excellent condition. The operation actually was a subtotal thyroidectomy. There was found at operation a very small right lobe, also an enlarged isthmus, a moderately sized pyramidal lobe on the left and a large left lobe. The patient did not long continue to do well after operation. She became gradually weaker, her pulse and temperature steadily climbed and she died the third day after operation. Unfortunately no autopsy could be obtained.

Finally a very important finding was that the pathologic examination of the thyroid showed no evidence of hyperplasia, merely the picture of colloid goiter, or so-called involution. As we look back over this case we can not escape the feeling that the operation was very likely not indicated. We learn by our errors. One error here was certainly in terminating the period of observation before the response to iodine or lack thereof had been definitely established. But even had this been done we might still have found ourselves in difficulties. How would we have interpreted a persistently high metabolic rate in spite of full iodination? One interpretation would have been that thyrotoxicosis was not present. One cannot, however, say categorically that failure to respond to iodine absolutely excludes overactivity of the thyroid. There are cases, undoubtedly thyrotoxic, who fail to show an iodine response, perhaps because the iodine is given at a time when their thyrotoxicosis is undergoing natural intensification. Mrs. B.'s story would have been consistent with such an interpretation. Had a good response to iodine been obtained, we should have felt that the indication for operation was much clearer. It is a pity that we didn't carry on long enough to give an opportunity for an unequivocal answer to our test. It is doubtful whether, had we left her unoperated, she would have lived very much longer. The cardiologists' opinion was that her outlook without operation was distinctly poor. That was one reason why it seemed rational to take a fairly desperate chance. In retrospect I regret that an operation was undertaken. I should rather have had her die unoperated than apparently as a result of surgery. The question also comes up as to whether multiple operation might have been better for her. I think this is possible, but not likely. It is my belief that the same outcome would have obtained had only a small portion of the goiter been removed as a preliminary procedure. This, however, is a point which cannot be settled.

Let us pass now to the case of Mrs. M., which I should like to contrast particularly with the case of Mrs. B. Mrs. M., a widow of fifty-nine, entered the hospital on November 29, 1934. She came in complaining of nervousness and fatigue for several months, emotional instability and recent weight loss. On physical examination she showed a warm, moist skin, definite tremor of her fingers, an enlargement of the isthmus and left lobe of the thyroid, but no eye signs characteristic of exophthalmic goiter. It was not possible to say, on the evidence which she presented, that thyrotoxicosis was present but there was a very definite suspicion of it. On November 30 her basal metabolic rate was found to be +49 and it was determined to conduct a diagnostic test with iodine. After iodine had been started the following metabolic rates were obtained: December 1, +47; December 3, +37; December 4, +42; and December 5, +40. On the latter day iodine was omitted. On December 10 the metabolic rate was +28; on December 12, +48; on December 13, +34; on December 14, +39; on December 15, +38; on December 17, +32 and on December 18, +32. On December 21 iodine was started again—potassium iodide, 10 minims once a day. On December 22 the metabolic rate was +46, on the 26th it was +40, on the 29th it was +43, on the 31st it was +31, on January 2, 1935, it was +30 and on January 4 it was +31. In other words, there was absolutely no indication that her condition was better while taking iodine than while not taking it. The iodine test was frankly negative. Nevertheless, it was felt that the clinical picture better fitted thyrotoxicosis than anything else and as the patient was not improving it was finally decided to resort to surgery. On January 5, 1935 a subtotal thyroidectomy was performed, which the patient stood very well. A considerable portion of both lateral lobes and isthmus was removed. The histologic examination of the tissue removed showed the type of hyperplasia characteristic of exophthalmic goiter with considerable colloid storage, that is to say involution. The patient made an uneventful recovery and on the 16th of January her metabolic rate was +2.

Mrs. B.'s case and Mrs. M.'s case furnish some interesting similarities and contrasts. The metabolic rates of the two were running at about the same level and in neither case did we establish any improvement as a result of giving iodine. We held off on Mrs. M.'s operation for a considerable period of time, largely because of the experience with Mrs. B. I felt that the failure to respond to iodine might, on the one hand, indicate that she wasn't thyrotoxic or, on the other, that if thyrotoxic she would be a poor operative risk. Both of these interpretations were incorrect. It turned out that she was definitely thyrotoxic and she did go through operation very smoothly. The presence of the serious heart disease in Mrs. B., of course, made the problem a much more difficult one than in Mrs. M., whose heart was apparently normal. Taken together, the cases may be said to teach us that while the iodine test is very helpful, it is not to be looked

upon as finally giving the absolute indication to treatment in all cases. In this respect it is not different from any other diagnostic test which we employ for a similar purpose.

We may now pass to another case, this one of proven thyrotoxicosis which presented some interesting difficulties. Mr. S., a widower of forty-six, entered the Massachusetts General Hospital first on November 26, 1934, transferred from the Boston Psychopathic Hospital, to which institution he had been sent two months previous for some definitely psychopathic manifestations. In addition to these, however, he had an array of signs and symptoms classic of exophthalmic goiter, and it was for that reason that he was sent to us. Examination and history further disclosed that he was suffering from rheumatic heart disease with involvement of both mitral and aortic valves, congestive heart failure and auricular fibrillation. He had moderate exophthalmos and lid lag, a very wild expression, a small firm goiter with very loud bruit, warm skin which was moist except in the palms which were dry, and slight edema of the ankles. The diagnosis of exophthalmic goiter was evident, and also the complication of rheumatic heart disease with decompensation, and apparent psychotic manifestations.

When I first saw him I felt he should be iodinated at once and operated as soon as he was ready. I felt that to rid him of his thyrotoxicosis might rid him of all his troubles—thyroid, cerebral and cardiologic. His metabolic rate on November 27 was +43 and on November 30, +53. He made a good response to iodine, his metabolic rate dropping to about +30 and his symptoms showing marked improvement. He had a good diuresis, losing 10 pounds of weight, which was presumably water, and showed an amazing improvement in mental state. We felt that he was ready for operation when he developed a throat infection which necessitated its postponement. To make a long story short, this dragged on and on and to it was added a certain amount of bronchial infection which caused him to run a temperature of low grade for many weeks. During all this period iodination and digitalization were maintained. Also during all this period his mental state seemed to be quite normal. It was our belief that his psychosis was purely a manifestation of thyrotoxicosis. Finally, on the 18th of March, 1935, his infection having subsided considerably, an operation was performed. Because the surgeon was worried about his condition on the operating table, the removal was confined to the right lobe and isthmus, in other words, hemithyroidectomy. Histologically this tissue showed slight hyperplasia and marked involution. This doubtless was due to the prolonged iodination. He was discharged from the hospital on March 26, afebrile and in pretty good clinical shape, but with a metabolic rate still running at a high level—in fact, higher than before his hemithyroidectomy. Metabolic determinations had not been made for some time prior to the operation because of the presence of infection. After the operation they were running in the neighborhood of +60. The circumstances of his admission required that he be returned to the Boston Psychopathic Hospital for further observation, although during his long stay in the Massachusetts General Hospital he had shown no symptoms which impressed us as indicating any mental abnormality except those described just after admission.

On July 19 he was readmitted to the Massachusetts General Hospital to have a second operation upon his thyroid. At that time he seemed to be in very good condition, had gained 28 pounds and was showing no evidence of psychosis, but still had a metabolic rate in the +60s. On reiodination this

dropped to a level of $+20$ and on August 6 his second hemithyroidectomy was performed. This he survived very well and on August 20 his metabolic rate was -2 . On August 22 it was -13 . Since then it has varied somewhat, often being within normal limits, but occasionally being up as high as $+28$. Following this second operation the patient became very much depressed and although this slowly improved, on October 18 he suddenly became violent and was discharged once more to the Boston Psychopathic Hospital.

This case brings up three factors which complicate the treatment of thyrotoxicosis: cardiac decompensation, mental decompensation, and respiratory infection. Indeed, we might add a fourth, namely, condition of the patient on the operating table which makes the surgeon unwilling to do more than a hemithyroidectomy.

I use the term "mental decompensation" advisedly. Just as the thyrotoxicosis adds a burden upon an already overloaded heart (overloaded by independent heart disease), so too may it add a burden to a brain potentially the seat of a psychosis and precipitate the same. As it has turned out this man seems to have a true chronic psychosis. Nevertheless, there is little doubt that the thyroid intoxication, working on such soil, created unusual havoc. Either the cardiac or mental complications in this case should be looked upon as indication for hastening operation to rid him of the extra burden which we have a way of removing.

The respiratory infection, upper and lower, which dragged on all winter, on the other hand, necessitated postponement of operation. However, by patiently waiting and maintaining iodination even this obstacle finally was overcome.

Finally, hemithyroidectomy is an unsatisfactory operation, because often it is necessary, as here, to follow it with a second resection. It is unpleasant, to say the least, for a patient to have his goiter out piecemeal.

This illustrates some of the vicissitudes of treatment. In spite of the several complications the outcome was good in all respects, except that there remained a residual psychosis, to which the psychiatrist gave the name of manic depressive.

The last case which I shall discuss presents a problem of quite a different nature. Mrs. S., a widow of sixty-six, entered the Massachusetts General Hospital first on June 22, 1922. Her story at that time was that for eight months she had gradually been losing strength and ambition and that occasionally she

had had attacks of dizziness. Furthermore, she had noted some swelling and puffiness in her face and her vision had appeared to her to be less acute. She had had increasing constipation and her skin had been getting dry and yellowish. These seemed to be the essential points in the history. Physical examination showed her to be obese and her face to present a strong suggestion of myxedema. The basal metabolic rate was determined on two occasions showing results of -34 and -35 . Her urinary and blood pictures were both within the range of normal. I was asked to see her in consultation, the particular question being, did I think she was suffering from hypothyroidism and if so, what therapy should she be given. My reply as it stands in the hospital record, dated June 28, 1922, is as follows: "Yes, in spite of certain atypical features, I think myxedema is very probably the trouble. I should get another metabolism test and then start her on $7\frac{1}{2}$ grains of Burroughs Wellcome thyroid and in a week have another metabolism test. After that regulate dose in accordance with clinical picture and metabolism level."

It may be worth while to comment on the dose of thyroid which I then advised. Seven and a half grains is a perfectly proper dose of Burroughs Wellcome thyroid. Since this firm gives its dosage in terms of fresh gland it is different from the dosage which would be used of a brand of thyroid which conforms to the United States Pharmacopeia. It appears to be the total organic iodine content which determines the physiologic potency of thyroid preparations. Our study of various commercial brands of thyroid indicates that the following are approximately the same both as to iodine content and as to physiologic potency: Burroughs Wellcome, 5 grains; any U. S. P. brand such as Armour's, Lederle's, Hynson, Westcott and Dunning's or Lilly's, $1\frac{1}{2}$ grains; or Parke, Davis, 1 grain. Therefore, the dose that I advised of Burroughs Wellcome thyroid would be equivalent to a $2\frac{1}{2}$ -grain dosage of any U. S. P. preparation.^{7,8} This is a little larger ration of thyroid than we advise at the present time. Our present custom is to use about 1 to $1\frac{1}{2}$ grains of U. S. P. thyroid. In 1922 we rather felt that it was desirable to give enough thyroid to raise the metabolism to standard. At present we are content merely to rid the patient of symptoms, which can be done with such doses as I have just mentioned. Under these circumstances the metabolic rate is apt to be in the neighborhood of -10 to -15 .

Mrs. S. was placed on the dose of thyroid which I advised and her myxedematous manifestations cleared up. Thyroid was begun on June 30, 1922 and six days later her metabolic rate had reached -19 . She was kept on this dose of thyroid until July 10, when it was raised to 12 grains of Burroughs Wellcome per day. She was discharged from the hospital on July 15, 1922, and on July 28 when she came into the clinic her metabolic rate was found to be -2 .

She was seen from time to time in the clinic and remained well, thyroid therapy being continued. In February 1923 her metabolic rate was -3 and in April of the same year it was -4 . She then was lost sight of for a period of eleven years until December 2, 1934, when she was again admitted to the ward, sent in by a private physician. The story at this time was that she had continued taking thyroid somewhat irregularly. One year before this time she had begun to notice swelling of her ankles, which had gradually increased. Seven months before she had become weak in the legs and had massive edema which made it hard for her to get about. At this time, she stated, her physician told her she had heart and kidney trouble. He put her back on thyroid, but she says that it didn't give her much relief. At the same time she was put on diuretics. Two months prior to the last entry she began to have increas-

ing thirst and increasing micturition. Finally her physician told her that she had diabetes and sent her into the hospital.

Physical examination showed her to be very obese, with somewhat dry skin which had a faint yellowish tinge. Her heart was somewhat enlarged with a rough blowing systolic murmur heard loudest at the second right interspace. The liver edge was felt $2\frac{1}{2}$ fingerbreadths below the costal margin and there was marked pitting edema of both legs. Her urine showed a moderate amount of sugar and her fasting blood sugar on several occasions was over 200 mg. My note on December 14 was as follows: "She apparently stopped thyroid about two months ago. She probably is coasting downhill metabolically. Now has -25 basal metabolic rate which is a level of slight symptoms. If kept off thyroid, presently she will have symptoms. I should give her no thyroid till symptoms show up and then put her on a very small ration, say $\frac{1}{2}$ grain (U. S. P.) once daily." I saw her again on January 4, and made the following note: "She still presents no clinical evidence of myxedema although off thyroid. Her diabetes is controllable thus far by diet alone. Her fasting blood sugar level is gradually falling. She may be continued off thyroid until clinical evidence of myxedema turns up." On January 8 Dr. J. H. Townsend, chief of our Diabetic Clinic, saw her and made the following note: "It seems as if she could be managed without insulin when she goes home. She is losing weight gradually on her present diet which should be continued pretty strictly." On January 11 she was discharged with a diagnosis of myxedema and diabetes mellitus. She was discharged with no medication and with a diet of C. 82, P. 58, F. 64. Her metabolic rate at this time was -23 . We didn't see her again until August 26, 1935, when she was readmitted to the hospital. She had grown progressively weaker, had increasing constipation, puffiness of her face, dryness and scaliness of her skin, decreased tolerance to cold and diminution in the acuity of hearing. On physical examination she now had, in contrast to the previous entry, the appearance of full-blown myxedema. She was very bloated, with sallow yellowish complexion, round puffy face, coarse hair, sparse eyebrows, slow thick speech and big tongue. Her metabolic rate on August 29 was -30 and on August 30 -34 . Her urine, however, showed no sugar and her blood sugar was 100 mg. I saw her on September 4 and made a note as follows: "She is definitely myxedematous now and apparently her diabetes is practically gone. Her heart also is behaving well. I believe the thing to do now is to place her on a small ration of thyroid, 1 grain per day. This will not totally abolish her myxedema, but should relieve it considerably and at the same time not be large enough greatly to aggravate her diabetes or cardiac weakness. I should carry on with thyroid alone in order better to evaluate its effect. Later if digitalis seems indicated it can be added."

These directions were carried out. She was placed on a ration of U. S. P. thyroid, 1 grain per day on September 6, after which basal metabolic rate determinations were as follows: September 12, -34 ; September 16, -26 ; September 17, -32 ; September 21, -23 ; September 24, -19 ; and September 29, -23 . She brightened very noticeably during this time and the myxedema facies disappeared. The fasting blood sugar had risen to 169 mg. on October 4, although no glycosuria had appeared. The development of some mild angina pectoris led to the omission of thyroid on October 2, following which the angina disappeared and the basal metabolic rate dropped back to -29 on October 7.

On October 10 thyroid was resumed in smaller dosage, $\frac{3}{4}$ grain once daily. She has remained on this dose since and has kept essentially free from the symptoms of myxedema, diabetes or angina.

This case illustrates how two diseases may be inimical, one to the other. I do not mean that each aggravates the other, but that each has the effect of diminishing the intensity of the other. Thus, in this case, the more myxedematous the patient became, the less was she diabetic; and as her myxedema was relieved by thyroid, the more did she become diabetic. Also getting too far away from myxedema occasioned attacks of angina.

It will be recalled that Wilder⁹ and Blumgart¹⁰ have produced myxedema artificially as a form of treatment for severe diabetes. In our case nature has done something similar, except that the myxedema antedated the diabetes. The therapeutic problem in such a case is an interesting one, namely, so maneuvering as to steer between the Scylla of myxedema and the Charybdis of diabetes. By the use of a smallish dose of thyroid this was accomplished successfully.

CLINIC OF DR. CONRAD WESSELHOEFT

HAYNES MEMORIAL HOSPITAL FOR CONTAGIOUS DISEASES,
MASSACHUSETTS MEMORIAL HOSPITALS

TREATMENT OF SCARLET FEVER AND DIPHTHERIA*

SCARLET FEVER

THE treatment of scarlet fever resolves itself primarily into a consideration of serum therapy, the theories of its applicability, and the results obtained from its administration in the course of the disease. The surgical complications which arise in its course will be touched upon only insofar as they concern the physician in attendance. A consideration of the origin and nature of the complications is an essential background for treatment, whether medical or surgical. Unfortunately, our knowledge in this respect is far from being satisfactory; consequently, our ideas must always be subject to rearrangement when theories are not substantiated by clinical experience. This statement applies equally to the medical man and to the surgeon who venture to deal with the problems of scarlet fever.

SERUM THERAPY

It is necessary to bear in mind that scarlet fever is an expression of a reaction to the invasion of certain strains of hemolytic streptococci. These strains have two very distinct properties. The first is peculiar to these particular strains, namely, the toxin-producing property. The second is the

* The author has purposely avoided detailed accounts of cases of scarlet fever and diphtheria because of the wide variety of manifestations exhibited in these diseases, and also because the practitioner who is interested in this subject can easily call to mind from his own experiences cases in which the subject matter of this article applies.

pyogenic or pus-forming property, which is shared by hemolytic streptococci in general.

The toxins of the scarlet fever strains produce the primary inflammation of the fauces, the enanthem on the soft palate, the strawberry tongue, and the rash on the skin. The rash consists of capillary dilation with enlargement of the papillae, and is associated with a tendency to minute hemorrhages according to the grade of toxicity in the individual attacked. These ruptured capillaries are most pronounced in the folds of the axillae and groins. We are justified in the inference that there is coincidental endothelial cell damage along with this process, and that the results of this damage may play a part in the subsequent course of the disease. The symptoms of vomiting and fever accompany the toxemia. In this connection Hektoen¹ has observed that "the toxin of scarlet fever streptococci is something more than erythrogenic" in that in susceptible persons it produces other symptoms than those by which we diagnose the disease. This, in brief, is the picture produced by the toxins of these scarlet fever strains.

It is the isolated toxin, or a combination of these toxins, which serves for the Dick test and immunization purposes, and by which we obtain antitoxin from the horse. While it was hoped that bactericidal and antipyrogenic substances would be obtained in the antisera—especially by means of the Dochez method—clinical experience does not substantiate this to the degree in which our hopes were raised. Consequently the direct effect of antitoxin is confined to neutralization of the toxin. When antitoxin is used early enough, preferably in the first twenty-four hours and not later than forty-eight hours after the onset, the effect is usually dramatic in the relief of the toxic symptoms. On this point almost all experienced authors are agreed. The fever drops, the rash fades, and the throat is improved. In fact, it is a common experience to have these cases so greatly improved the following day that only traces of the disease are apparent. This same thing can be achieved by the administration of convalescent scarlet fever serum or by transfusion from a convalescent scarlet fever donor.

This brings us to an important point in the discussion. During the past fifty years the mortality from scarlet fever has been steadily dropping in America and England. Patients

rarely die from toxemia, but they suffer greatly and die from a wide variety of complications. Therefore, it is to the complications that we must turn our attention. It is in this field that we become aware of our lack of knowledge and the resulting disagreement as to the value of therapeutic measures.

The complications of scarlet fever may be divided into those which are of pyogenic origin such as abscess formation; and those which are not, such as arthritis, glomerulonephritis, and purpura hemorrhagica. Again, they may be divided into those which appear with the eruptive stage and those which take place after the acute symptoms have entirely subsided. Lymphadenitis, otitis media, sinusitis, and purulent rhinitis are common in the eruptive stage; yet they often appear rather suddenly at any time during convalescence. Glomerulonephritis and purpura hemorrhagica, however, are more apt to come on abruptly somewhere around the fourteenth day.

The significance of these two classifications of complications is appreciated by the clinician, although he has no clear explanation in mind as to why otitis media, for instance, can take place at the onset when there is every reason to suppose that it is a direct extension of the throat infection; and why exactly the same type of otitis media can occur in the third week of convalescence when, to all appearances at least, the throat and nose are normal and the patient seems on the high road to recovery. This latent phase in scarlet fever is a most perplexing problem, and has called forth an array of theories, none of which is satisfactory. In fact, I am not at all sure that the origin of the early complications is as simple as we try to make it. I have observed an earache with injection of the drum following each weekly injection of the toxin during immunization. Seiferth² goes so far as to say that in every case of scarlet fever, hyperemia of the tympanic cavity takes place in the eruptive stage. However, the possibility which all this implies as to the toxic element in the initial stage of early otitis media does not help us to understand the origin of late otitis media when the toxin, to all appearances, is thoroughly neutralized. Furthermore, otitis media can originate while a patient is experiencing that beneficial effect from the early administration of antitoxin. Thus, while complications can well arise from the direct action of

the toxin alone, they may also arise from the penetrating and pyogenic properties of these streptococci. These latter properties may possibly be indirectly related to endothelial cell damage. The effects of this damage might occur early or late in the disease and would not be influenced by the presence of antitoxin, whether spontaneously or artificially supplied.

The effect of serum therapy on the complications of scarlet fever may be divided into two categories. First, it has no appreciable effect on complications, once these have made an appearance. Second, its early administration is not attended universally with any marked lessening of complications. This statement bears qualification. Antitoxin is not of the same standard potency the world over. In spite of the greatest care in preparation, standardization, and aging, different lots of serum from even the same laboratory vary in their efficacy and in their incidence of serum sickness. Convalescent serum varies greatly in its efficacy, and it is not standardized. If pooled serum is used, the antibodies for the offending strain may be sufficiently diluted by the mixture to be quantitatively ineffective.

While antisera are generally effective in combating toxemia, the divergent results in preventing complications can, at least in part, be attributed to the type of serum used, the dosage, and the method of administration. At the scarlet fever congress in Königsberg in 1928 the great majority expressed the opinion that antisera did not prevent complications.³ More recently, numerous European and the majority of American and English authors report favorable results in this respect in reasonably large series of cases. Toomey⁴ has pointed out that in 4611 serum-treated cases recorded in the literature only 26 per cent were controlled by cases from the same epidemic. Toomey found slightly more complications in his serum-treated cases than in the untreated. Nor is his unfavorable experience unique. Kohn and Josey⁵ found intramuscular use of Dochez serum ineffective in preventing complications. Cinca⁶ and his coworkers in Roumania, where the disease is still severe, Rolleston⁷ in London, and Gabriel⁸ in Vienna, where the disease has lost much of its toxicity, give little credit to antitoxin in this respect.

At the Haynes Memorial in an analysis of 10,000 cases of scarlet fever we have compared by two different methods the incidence of complications with and without serum. Using the pre-serum period as a control, we found 15 per cent more complications than in the period where serum was given. During the serum period about one third received serum, and these showed 5 per cent more complications than those receiving no serum. In the first method, we have to discount the fact that the disease has been growing less severe; in the second, we have to recognize that all the very mild cases received no serum. These two factors make it difficult to evaluate the effect of serum therapy on the incidence of complications, in spite of the very dramatic improvement in the toxic symptoms shown by so many of these serum-treated cases.

On the other hand, Place,⁹ Gordon¹⁰ and his coworkers,¹¹ Stevenson¹² and his coworkers, Craig,¹³ Friedemann,¹⁴ Hunt,¹⁵ and Banks¹⁶ have reported decidedly favorable results in preventing complications. Hoyne¹⁷ and Bahov¹⁸ have found convalescent serum definitely effective in preventing complications.

Granting that complications have been materially lessened in the hands of most competent observers, there is still to be considered the disadvantage of serum sickness from antitoxin. Numerous authors have pointed out that the routine use of antitoxin in all cases causes more hours of illness in the mild cases than these would ordinarily suffer if not given serum. Consequently we must weigh the good we expect to accomplish with the possibility of serum sickness. Having had three severe Arthus reactions from scarlet fever antitoxin during the past winter, my enthusiasm has been somewhat dampened. It is difficult to reconcile the remark of Banks¹⁶ that he encountered no serum-sensitive patients in his intravenous series with a later remark in the same article that 3 cases suffered from shock after one lot of serum. Place⁹ has seen 125 Arthus reactions from antiscarlet and antitetanus serum. The unbridled enthusiasm of some authors^{19, 20} reminds me of my own first impressions.

In talking with others of hospital experience I find a growing tendency to reserve serum therapy for severe cases and to favor convalescent serum. There are two disadvantages in convalescent serum. First, as has already been mentioned, it is not standardized, and it sometimes does not contain enough antibodies for the offending strain. Second, it is not obtainable by the general practitioner, except where there are serum centers, as in Detroit and Chicago. Elsewhere the

general practitioner is at the mercy of those who control the supply.

Lichtenstein²¹ reports an interesting analysis of 1000 cases equally divided into antitoxin, convalescent serum, and no serum. He attributes his infrequency of serum sickness to the fact that the Swedish serum is not concentrated. The incidence of complications was only very slightly reduced in both of the sera groups.

It is to be hoped that a marketable product will some day be achieved which can be relied on to prevent complications and not to produce serum sickness. But until this is accomplished, many difficulties will have to be overcome and much more will have to be learned about the nature of scarlet fever pathology.

It is necessary to speak of one more measure, namely, the transfusion of blood from convalescent donors.²² This has been used successfully in very severe cases on admission to the hospital, especially in those septic cases which do not yield to antitoxin and convalescent serum. Schultz²³ reports a case which did not respond to a full dose of antitoxin but the next day was greatly helped by a 300 cc. transfusion from a convalescent scarlet fever donor. There are other factors in this transfused blood besides antibodies to counteract the toxin. Very large doses of convalescent scarlet fever serum have been used in a variety of streptococcic infections not of scarlet fever origin.²⁴ It would seem probable that the lucky strikes reported in some of these cases result from those other factors in the blood serum which are quite apart from and probably independent of scarlet fever antitoxin. The use of anti-streptococcic human sera for such cases selected on a titer basis would save convalescent scarlet fever serum for its more specific indications.

While the subject of patents hardly belongs under the head of progress in our knowledge of a disease, it is worthy of mention that the Dick patent covering the toxin and the antitoxin is controlled by the Scarlet Fever Committee in Chicago, through which licenses for manufacture and distribution are granted. The Dochez N. Y. 5, as well as all other strains derived from scarlet fever, appears to be embraced by the wording of this patent. The Dochez antitoxin patent is held by the Presbyterian Hospital in New York City. One lawsuit has resulted already over these products, and an unwholesome atmosphere has been created of which the practitioner and bacteriologist are conscious. The Dicks' discovery remains a monumental achievement in

medical science. Their subsequent act of putting a legal fence around it seems to have partially obstructed the view.

TREATMENT OF COMPLICATIONS

Cervical adenitis: the most frequent complication in its mild form. Five per cent of the cases develop large painful glands which subside without suppuration, while another 4 per cent suppurate. Local heat affords relief to one individual, while cold affords some degree of comfort to another. We need not be guided by the idea that cold prevents suppuration or that heat draws it to the surface. Pointing takes place toward an ice bag in the same proportion of cases as it does toward a hot water bottle or a poultice. Deep abscesses should be opened by a surgeon; but in those which point to the surface, it is well to let them point and then to make a small nick and express the pus.

Purulent rhinitis is very common in both the early and the late septic conditions. It is also, of course, associated with sinusitis, and as such—when hemolytic streptococci are present—is the most common source of spreading scarlet fever. In this connection Gordon²⁵ has further established that there is no advantage in the continuation of *quarantine* of uncomplicated cases beyond the usual period because of positive hemolytic streptococcus cultures. *Release cultures* appear to be of value only when purulent discharges are present. Gentleness is essential in any attempts to use drops, sprays, swabs, or suction.

Otitis media: incidence 12 per cent. Simple otitis is more frequent than is commonly supposed, but is difficult to differentiate from the onset of the suppurative type. It is not prevented by cod liver oil²⁶ or carotene.²⁷ Paracentesis is indicated where there is a severe pain, a bulging drum, or an inadequate opening. In a series of 14,733 cases of scarlet fever Williams²⁸ found that surgical *mastoiditis* followed in 6.6 per cent where paracentesis was done before rupture, in 7.7 per cent where paracentesis was done after rupture, and in 9.3 per cent where spontaneous rupture took place and no paracentesis was done. From which we can draw our own conclusions as to the value of paracentesis in preventing mastoiditis. Kopetzky²⁹ says: "It is well recognized that paracentesis does not prevent the development of mastoiditis

. . . [which] is dependent on the bone structure of the tympanic and mastoid areas and on whether or not the original lesion attacks the epitympanic space." In some cases mastoid destruction goes on very rapidly and operative delay is dangerous. An ear which suppurates profusely for three weeks should be regarded as probably due to a mastoid abscess regardless of fever or mastoid tenderness. An x-ray is of great value here. Operation in these cases saves the hearing, sometimes life, and shortens the period of quarantine. Removal of the tonsils and adenoids may be accomplished during scarlet fever with less danger than is commonly supposed, and often with decided benefit to the patient.

Sinusitis may occur with the prodromal symptoms of scarlet fever or at any time in the course of the disease.³⁰ Early surgical interference is to be avoided. Empyema of the ethmoid sinus may penetrate the orbit and produce redness and edema of the upper lid and push out the eyeball. This condition sometimes subsides of itself, but even in the severe forms, under skillful surgical care the prognosis is good. A frontal sinus abscess may burrow into the subdural space in rare instances.

Nephritis in a mild degree is a frequent accompaniment of the eruptive stage. Acute glomerulonephritis, especially of the hemorrhagic type, varies in different epidemics from below 1 to above 12 per cent. It occurs most frequently during the third week in an abrupt manner, and uremia may come on without previous warning in the urine or in the chemical analysis of the blood.³¹ Chilling seems to be responsible in a few cases.³² It was formerly thought that a milk diet prevented nephritis. It is now recognized that the incidence is slightly greater if too much milk is supplied. Nor is it the protein content of the milk which is now accused but the fat, which is thought to impair hepatic function and indirectly favor renal inflammation.³³ Jürgens³⁴ suggests that potato be avoided because of the potassium content, but the facts are entirely against such an assumption. A mixed diet suited to the age and the presence of fever is all that is required. Milk should not be taken in excess.

Thenebe³⁴ and his coworkers classify glomerulonephritis as "allergic manifestations." The question immediately arises

as to whether the toxin is allergenic. Hooker³⁶ informs us that the purified toxin is not known to have allergenic properties; it has not been shown to sensitize the skin. Streptococcal nucleoprotein, on the other hand, has this property. Shall we assume, then, that the initial lesion is a kidney infection? Duval and Hibbard³⁷ in their animal experiments come to the conclusion that the glomeruli are first affected by the toxin, while the interstitial lesions result from infection. These conclusions, however, are based on animal experiments, and there is no ground for assuming that free toxin in any appreciable amount exists in the third week of convalescence. It is necessary to mention all these ideas in order to show what we do not know about nephritis. When we realize this, we can proceed to treat the nephritis in the usual and accepted manner.

Endocarditis (rare).* Place³⁰ describes the characteristic heart damage as a benign endocarditis. In recent years he has found this condition in less than 0.1 per cent of his scarlet fever cases, though formerly as high as 0.5 per cent. The diagnosis is based on the usual findings of fever, cardiac murmurs with tachycardia, and changes in the size of the heart, arthritis being a usual accompaniment. He found that it usually appeared in the second or third week, persisted a few weeks, and subsided without further damage. A murmur during diastole, or a murmur replacing a heart sound, or persisting through systole, he considers to be indicative of structural change. While he recognizes that the crippling effect varies as in other forms of endocarditis, he is of the opinion that it is slight as compared with rheumatic fever.

This brings up the point mentioned by White,⁴⁰ that it is difficult to determine to what extent scarlet fever is a cause of chronic valvular heart disease, because acute polyarthritis, "apparently rheumatic fever," occurs in about one-half of the scarlet fever cases where endocarditis or pericarditis develop.

Salinger and Leonard⁴¹ refer to the endocarditis of "allergic" origin, but the term is not generally accepted. Stolte,⁴² on the other hand, gives us a very practical classification of scarlet fever heart conditions. The first group comprises those

* Zischinsky³⁸ found only 10 among 20,000 hospital cases of scarlet fever in Vienna.

benign conditions which Place has described; the second, those with arthritis, pericarditis, and the sweating so characteristic of rheumatic fever; the third, malignant endocarditis. In the first group, rest in bed is, of course, essential, but no medicinal treatment is indicated. Salicylates are helpful in the second group. Transfusions may be tried in the malignant type. The usual indications for digitalis are rarely present in the acute stage; and when they are present, pericarditis or septicemia is apt to interfere with any good that may be accomplished.

Purpura hemorrhagica (rare) may occur in a mild form early, but in its severe, abrupt, and fulminating form appears about the fourteenth day. The purpura may appear only on the lower part of the legs or arms. Again, it may suddenly involve the entire cutaneous surface and the mucous membranes, with a fatal outcome within forty-eight hours of its onset. Like acute glomerulonephritis, it appears to have no relation to the severity of the initial scarlet fever rash. Furthermore, it bears no relation to a previous history or family history of a purpuric diathesis.⁴⁸ Box⁴⁸ considers this complication to be due to a supersensitive stage in the course of establishing immunity. We might well speculate on its origin from the results of endothelial cell damage in the eruptive stage. In severe cases transfusion is indicated, and a convalescent scarlet fever donor may be used.

Appendicitis (rare). When this occurs in scarlet fever it is apt to be of the abrupt and fulminating type. Any delay in calling in surgical aid may result in rupture and peritonitis. If the appendix has not ruptured, a drain should not be used, as the wound will then surely slough wide open later. The wound should be closed tight, as in any clean case, even if the rash is in full bloom. There is a strong tendency for clean wounds, such as in a hernia operation, to slough wide open if scarlet fever supervenes on the operation. We have found that closing tight an unruptured appendectomy wound affords a very good chance of primary healing. It should be the duty of the attending physician to bring this forcibly to the attention of the surgeon called in.

Empyema (rare). When this develops in the course of scarlet fever, the closed method, even in adults, has been

found to be the safest initial surgical procedure, even though it sometimes has to be followed by a rib resection. One or more tappings may be advisable to favor the walling-off process. Allowing a large amount of serum to accumulate is to be avoided. The determination of the presence of empyema in scarlet fever does not demand the haste of surgical intervention as in appendicitis.

The initial responsibility in all these surgical complications rests with the attending physician. He must learn to recognize their importance, and through his knowledge of scarlet fever he should continue to be an active adviser to the surgeon throughout the case.

DIPHTHERIA

SERUM THERAPY IN MILD AND MALIGNANT DIPHTHERIA

Recent advances in our knowledge regarding the serum treatment of diphtheria deal with the size of the dose and the methods of administration. The prevalence of the malignant type of the disease in Austria, Germany, Scandinavia and England has stimulated a lively interest in this subject. These malignant cases occur sporadically in America, and their relatively poor response to vigorous antitoxin therapy has caused consternation abroad even to the point of downright skepticism as regards the value of this agent. To my mind, this attitude is wrong. Recognition of the possibility of the severe type should prompt us to avoid any unnecessary delay in treatment, instead of permitting us to adopt the nihilism emanating from Vienna (Zischinsky).¹

The mechanism of antitoxin therapy is essentially a protective or preventive one. If the clinician grasps the fact that the curative virtue of antitoxin is based on its protective value, he will not allow himself to become confused by the recent unfavorable reports of antitoxin therapy in this disease, or by the divergent opinions regarding dosage and methods of administration.

Let us start with the undeniable fact that antitoxin is as capable of neutralizing the toxin as water is capable of putting out a fire. The basis for this statement lies in the very method by which a unit of antitoxin is standardized. But here we are immediately confronted by the statement of Friedberger² that the natural diphtheria in man is as different from the toxin diphtheria in the guinea-pig as a man is from a guinea-pig. We admit the logic of this only to a certain extent. We are well aware that barriers of resistance exist in the mucous membranes of the upper respiratory tract of man which delay invasion and tend to prevent absorption of the toxin. These barriers, however, which vary so greatly in different individuals, may actually augment the danger because they are the cause of delays in recognition of the disease. This may

sound paradoxical, but it is not. A smouldering fire is potentially capable of bursting into flame. Diphtheria may smoulder, so to speak, and go out of itself, or it may take on a malignant aspect at the very start or after a period in which these barriers have tended to hold back the disease process. The amount of antitoxin necessary to neutralize the toxin in a given case depends on whether the process is being held at bay, and on whether a malignant aspect is manifest, and if so, how far it has proceeded.

In neutralizing the toxin in the guinea-pig, the antitoxin is usually given simultaneously. A dose which will save a guinea-pig if administered within fifteen minutes of the toxin will not suffice if given later. In fact, if we wait two hours and a quarter, a dose one thousand times as great will not suffice to save the animal.³ When we realize that 1000 units of antitoxin to a guinea-pig corresponds to 100,000 units for a 50-pound child, we can easily understand why enormous doses of antitoxin so often fail to save malignant cases. The appreciation of these facts shows the difference as well as the relationship of experimental toxin diphtheria in the guinea-pig and the natural disease in man. It emphasizes the important part that time plays in the protective action of antitoxin.

It thus becomes obvious that the time element in conjunction with the stage of the disease process constitutes the basis for gauging the dose of antitoxin. Furthermore, we must bear in mind that antitoxin therapy is essentially protective. It does not dissolve the membrane. It does not destroy the bacilli. What it does is to neutralize the toxin, and thus, by protecting the tissues, it allows the operation of those other natural forces of the tissues, so vitally concerned with the recovery of the patient.

With these facts in mind we can understand why the question of the required dosage in cases of diphtheria cannot be met with definite answers. You might as well ask the chief of the fire department how much water on the average he needs to put out a fire. You know perfectly well that a pail of water will be enough at the start, but once it gets under way the answer becomes involved. If the house burns down, one does not say that water doesn't put out fire. This may

all seem so elementary as to appear entirely unnecessary. But when clinicians in posts of authority are voicing their disbelief in antitoxin as a result of their experiences with malignant diphtheria, it is time to revert to first principles.

Dosage, then, is dependent on the time element. It also depends on the manner of administration. The intravenous route gives us the most prompt action, but two-thirds of the antitoxin so given leaves the blood within twenty-four hours.⁴ Thus, if conditions warrant this method of approach, it is desirable to inject another dose into the gluteus muscle, from which site it will be continually given off, reaching its maximum concentration in the blood at the end of twenty-four hours. The subcutaneous route is the slowest.

Park⁵ in New York advocates a scale of dosage which varies from 3000 to 60,000 units. In Boston we have been accustomed to employ approximately twice as much. Recent accounts from Paris,⁶ where the intramuscular and subcutaneous routes are used, advocate a scale running from 45,000 to 300,000 units. Bie⁷ in Copenhagen has given as much as 500,000 units. Bie influenced many of us by his high scale of dosage, which was accompanied by an extraordinarily low death rate; but this was before the wave of malignant cases, which, in spite of this high dosage, has brought about a high death rate.⁸ In Stockholm a high dosage scale was carried out from 1925 to 1928, but on analyzing the results Lichtenstein⁹ found that the mortality in the severe uncomplicated faucial type remained the same as it had been over a previous period with much smaller doses.

From these hospital statistics we are confronted with the fact that the routine use of the larger doses shows no apparent advantage as determined by the yearly mortality and the incidence of postdiphtheritic paralysis. In other words, our attempts to protect well advanced severe cases have perhaps carried us beyond the maximal dose which could be effective. We must not lose sight of the fact that hospital mortalities are dependent on the promptness with which outside physicians recognize diphtheria. This applies not only to the above-mentioned smouldering type, but more particularly to the malignant type, where the time element becomes such a crucial factor.

From the point of view of the clinician the malignant type offers no new problem. It has been constantly with us in the sporadic form. Its increase would appear to result from unknown environmental conditions affecting man's resistance. It is not a new disease but a virulent form of the same one, occurring in parts of Europe as 10 per cent of the diphtheria cases. In Berlin the death rate in this type has been as high as 50 per cent.⁸ Bacteriologically it represents a virulent strain with increased penetrating and increased toxin-producing properties. So fulminating is it at its worst that large doses given during the first twenty-four hours have proved ineffective. I have seen one case referred to us by one of my former interns who gave all the available antitoxin (30,000 units) before sending it to the hospital, where the child received 130,000 more units but died within thirty-six hours of the onset. No one was to blame. Antitoxin was simply ineffective because it could not protect against this overwhelming infection. To say that the antitoxin was ineffective as a protection by no means implies that it was inert. Animal experiments with these new strains give unsatisfactory results because animals may react more unfavorably to the milder strains than to the malignant strains.¹⁰ To suggest that malignant types are due to mixed infections with a streptococcus⁴ is to sidestep the issue. The streptococcus is found also in the blood of malignant smallpox cases. Where antistreptococcic sera have been used in conjunction with antitoxin the mortality was 55 per cent.³ It is true that a mixture of scarlet fever and diphtheria was an ugly combination before the days of antitoxin, but it is no longer so formidable. If an antitoxin derived from a malignant strain¹¹ proves more effective clinically in these cases, we shall still be confronted with the time element of its administration. Since the regular antitoxin is capable of neutralizing the toxin of the malignant strains, every effort should be used to apply it early. In these cases it does not depend on the day of the disease but on the hour.

Another factor which has come to light in recent literature tends to bring us back to first principles, and also suggests that we may be overstepping the mark in dosage. In 1918 Bingel¹² gave us a surprise when he found that cases

treated with "normal" horse serum did as well as those given equal doses of antitoxin. He later informed us that the "normal" serum was obtained from horses used for antitoxin purposes in which the antitoxin titer had fallen to a very low level. Recently Hottinger and Toepfer⁸ have concluded that they have reduced the mortality of malignant cases in their hospital in Düsseldorf from 43.5 per cent to 17.0 per cent (not including those moribund on admission) by giving 4000 units intravenously and repeating this dose intramuscularly two to four times a day with interspersed doses of this low titer antitoxin. Naturally, the idea of nonspecific protein therapy was brought forward as an explanation of these results. It has remained for von Bormann³ to establish the fact that nonspecific protein therapy is not concerned with the results recorded by Bingel, Hottinger and Toepfer. By injecting various strains of diphtheria bacilli into the conjunctival sacs of guinea-pigs he has tested the relative efficacy of these three sera. With antitoxin the animal is saved, and sometimes the eye is not damaged. With low titer antitoxin the animal is sometimes saved, but the eye is lost. With really normal horse serum there is a 100 per cent mortality. Over 300 animals were used. Since the guinea-pig may be protected by serum with a very low antitoxin content, he argues that the use of the original method of giving 1000 to 2000 units in mild cases—doses with which antitoxin won its first laurels—is not so far wrong as we have come to think.

In other words, recent laboratory and clinical results suggest that the mild cases may be sufficiently protected by doses of 500 to 1000 units, that malignant cases, if treated early, may often be protected by frequently repeated doses of 4000 units, and that a certain number of malignant cases reach us too late to be saved from a fatal outcome by any amount of antitoxin. With this in mind, one is inclined to play safe by allowing plenty of margin in the milder cases and to persevere vigorously in the malignant ones with the hope that treatment may have been begun in time.

Thus the practitioners whom we were wont to accuse of giving inadequate doses may derive some satisfaction from the new light on this subject, while others like myself are prompted to recede cautiously from the maximal doses we

have been in the habit of using. The theory that one large enough single dose at the beginning should be our aim, as advocated by Park and Schick, still applies to the mild types, and Park's dosage scale appears to be vindicated. The frequent repetition of small or moderate doses in malignant cases would seem to be worthy of trial. Roughly speaking, the minimal dose is 3000 units subcutaneously. The maximal dosage is 500,000 units given intravenously and intramuscularly in repeated daily doses averaging 100,000 units. While any scale of dosage is unsatisfactory because it is incomplete, the following is a rough guide to be varied by the duration of the symptoms and their severity.

DOSAGE OF ANTITOXIN IN UNITS

Weight of patient.	Mild.	Moderate.	Malignant.
Under 50 lbs.	5,000	10,000	50,000
Over 50 lbs.	10,000	20,000	100,000

Antitoxin should not be used in the postdiphtheritic paralyses; first, because it does no good; second, because there is ample antitoxin in blood at this stage; and third, because of the danger of anaphylactic shock eight to nine days after the first dose.

While the protection which antitoxin affords to man is not to be compared to the protection afforded by active immunization, we must keep in mind that the early bedside recognition of diphtheria governs the amount of antitoxin required.

CLINIC OF DR. LEROY D. FOTHERGILL

FROM THE DEPARTMENT OF BACTERIOLOGY AND IMMUNOLOGY
AND THE DEPARTMENT OF PEDIATRICS, HARVARD MEDICAL
SCHOOL

SOME RECENT ADVANCES IN VACCINES AND SERUMS: A. REVIEW

INTRODUCTION

It is manifestly impossible in this communication to discuss completely all the topics which this title might suggest. It seems wiser, therefore, to limit this review to those topics which are relatively new and which are receiving considerable attention from the medical profession at the present time. The writer intends to express freely his own opinions of the relative merits of these several biological products. The topics which will be reviewed are: (*a*) whooping cough vaccine; (*b*) placental extract; (*c*) tetanus toxoid; (*d*) meningococcus antitoxin (Ferry); (*e*) staphylococcus toxoid, and (*f*) staphylococcus antitoxin.

WHOOPIING COUGH VACCINE

During the past few years two new products have received considerable attention for the prophylaxis of whooping cough. Furthermore, a few papers have appeared in recent years suggesting that a filtrable virus plays an etiological rôle in the disease. Since the etiological rôle of an organism in any disease should be definitely established before it is justifiable to use that organism in a prophylactic vaccine it will be well briefly to review the etiology of whooping cough.

Ever since hemophilus pertussis was first described by Bordet and Gengou¹ as the causative agent of whooping cough, occasional reports have appeared purporting to cast doubt on

the etiological rôle of this bacterium and suggesting that a virus may be a factor in the cause of the disease. The various arguments in favor of the virus theory have recently been summarized by Rich² as follows: (a) pertussis bronchopneumonia is an interstitial reaction, with mononuclear cells predominating, which is the characteristic type of histopathological response to virus infection; (b) pertussis results in a permanent immunity as in most virus diseases, whereas most bacterial diseases do not (Note: we might point out that several virus diseases are characterized by a very short immunity, *i. e.*, herpes labialis, the common cold, and influenza, and that prolonged immunity is supposed to follow some bacterial infections such as typhoid, cholera, plague, etc.); (c) *Hemophilus pertussis* is isolated only during the early stages of the disease; (d) intranuclear inclusion bodies have been described as occurring in the lungs of children dying of pertussis bronchopneumonia; (e) experimental transmission of the disease (Rich, 1932) has not been adequately demonstrated and thus Koch's postulates are not fulfilled.

Recently, Sprunt, Martin and Williams^{3, 4} have answered the argument of Rich that the mononuclear interstitial reaction in the lungs suggests a virus etiology. These investigators produced this type of reaction in the lungs of rabbits by the intratracheal injection of pure cultures of Bordet-Gengou bacilli. A similar bronchopneumonia was produced with the typhoid bacillus. Furthermore, the same type of reaction was produced by the intratracheal injection of various bacterial toxins (*staphylococcus aureus*, hemolytic streptococcus and diphtheria toxins). These authors found that these reactions could not be differentiated from that occurring in children dying of pertussis bronchopneumonia or from that caused in animals by the viruses of epidemic influenza and psittacosis.

Within the past few years McCordock,⁵ Rich² and McCordock and Smith⁶ have demonstrated intranuclear inclusion bodies in the lungs of children dying of pertussis, which they feel suggests the possibility that a virus may be the primary etiological agent. Rich does suggest that these inclusion bodies might be due to aspirated herpes virus. McCordock also reviews a few instances from the literature where similar

bodies were found in nonpertussis patients. Furthermore, the inclusion bodies described by Farber and Wolbach⁷ as occurring in the salivary glands of a considerable percentage of infants dying from a variety of causes are morphologically indistinguishable from the inclusion bodies described by the above authors in the lungs of patients with pertussis.

Because of these suggestions that a virus may play a rôle in the etiology of whooping cough some recent transmission experiments have been done which, in our opinion, offer very conclusive proof that *Hemophilus pertussis* is the sole etiological agent in this disease. It should be pointed out that in regard to the old transmission experiments cited by Rich² the dissociation of *Hemophilus pertussis* was not understood. At the time when these investigations were done it is likely that some of these experiments were carried out with avirulent strains.

Sauer⁸ inoculated (into the nose and throat) healthy young Rhesus and Ringtail monkeys with virulent Phase I cultures. In 8 out of 76 instances the animals developed a paroxysmal cough followed by vomiting of mucus after an incubation period of seven to twenty days. The organism recovered from one coughing animal produced the disease in another animal inoculated with it. This, of course, is not an entirely convincing experiment because of the very small percentage of positive results. In 1933, Macdonald and Macdonald⁹ reported a unique experiment on human volunteers. Four healthy boys whose medical histories were accurately known were used in these observations. Two of the boys had been vaccinated two months previously with the Sauer vaccine. The other two were nonimmune. The throats of all four were sprayed with the filtrate of the first generation of a freshly isolated culture. No symptoms developed. The boys were kept rigidly quarantined in a country camp. Eighteen days later a suspension containing 140 bacilli was dropped into the nose and throat of each boy. The nonimmune boys developed typical whooping cough with positive cough plates. The vaccinated boys remained free of symptoms and had no positive cough plates even though they were all kept together throughout the period of observation. These authors conclude that the Bordet-Gengou bacillus is the sole cause of whooping

cough and that active immunity is conferred by the injection of *Hemophilus pertussis* vaccine.

In Shibley's¹⁰ more recent transmission experiment the virus possibility was examined still further. This author carried a Phase I culture through 60 generations in order to be certain that a virus was not carried over in the culture. With this culture he succeeded in producing a typical train of symptoms in a chimpanzee. The animal was sacrificed and *Hemophilus pertussis* was recovered from various locations in the respiratory tract.

We have not reviewed the additional positive evidence pointing to *Hemophilus pertussis* as the sole etiological agent of whooping cough. We merely desired to point out the inadequacy of the virus theory of etiology. In our opinion the evidence points conclusively to *Hemophilus pertussis* as the sole cause of the disease.

Within the past few years there has been considerable advance in our knowledge of the biology and antigenic composition of the Bordet-Gengou bacillus which has an extremely important bearing on prophylaxis by vaccination. Lawson¹¹ and Leslie and Gardner¹² have shown that *Hemophilus pertussis* is capable of undergoing dissociation into serologically different variants, which have been termed Phases I, II, III and IV. Each of these phases probably possesses a different antigenic structure. The serological differences between these mutation forms probably accounts for the several types of pertussis bacilli described in the older literature. As far as we know now *Hemophilus pertussis* is a homogeneous species. Phase I is always hemolytic and is the form recovered in the disease. It is the virulent phase and corresponds to the "smooth" form in general dissociation nomenclature. Phases III and IV are "rough" or avirulent. The importance of this is that if any prophylactic vaccine is to be of value it must be made from Phase I cultures.

Innumerable attempts have been made in the past to actively immunize children with hemophilus pertussis vaccines. Such attempts have been almost uniformly unsuccessful. Even Madsen's¹³ unique experiences in the Faroe Islands are not entirely convincing. It is of some interest that in 1931 the Council on Pharmacy and Chemistry of the American

Medical Association removed pertussis vaccines from New and Nonofficial Remedies because there was no convincing evidence as to their value either prophylactically or therapeutically. In light of our present knowledge there are several possible reasons for the failure of these vaccines. Many of such vaccines were probably made from dissociated, avirulent cultures. Immunization generally was not done a sufficiently long time before exposure (in fact, in most instances such vaccines were administered either after exposure or during the early stages of the disease). Also the immunizing doses used were probably entirely too small.

In a series of communications during the past few years. Sauer^{14, 15, 16, 17} has described his experiences with his new type of whooping cough vaccine. His vaccine is prepared and administered in such a manner that the probable reasons for failure of the older vaccines are overcome.

Sauer's method of preparing and administering his vaccine is as follows. We quote excerpts from his papers directly. "Bacillus pertussis vaccine (1 cc. = 10 billion bacilli), is made from recently isolated, strongly hemolytic (Phase I) strains, grown on Bordet (potato-glycerin extract agar) medium made with freshly defibrinated human blood. To minimize the culture medium content, the forty-eight hour growth is scraped off and mixed with 0.5 per cent phenolized physiologic solution of sodium chloride. To insure purity, a stained smear of each surface growth is examined before it is harvested. After a week in the refrigerator (during which time it is shaken daily), the concentrated suspension is cultured for sterility on three successive days. After dilution with 0.5 per cent phenolized physiologic solution of sodium chloride so that 1 cc. contains about 10 billion bacilli, it is tubed, sealed and refrigerated until shortly before it is used."

Sauer has emphasized several essential points concerning the production of this vaccine which can be reiterated with profit. It should be made with freshly isolated, Phase I cultures. It is made with human blood medium because: (a) the organism is more apt to be maintained in its virulent phase on this medium; (b) foreign blood protein from the medium cannot be taken up with the vaccine. This eliminates any possibility of sensitization and subsequent hypersensitive reaction.

We feel that it is probably not essential to use human blood. So far as we know the organism will maintain its original antigenic structure on sheep or other blood as well as on human blood. The vaccine is not heat killed, which eliminates any possibility of antigenic change or reduction of antigenic potency due to heat denaturation, etc.

A total of 8 cc. or 80 billion bacilli are given in three bilateral injections at weekly intervals. They are given subcutaneously in the deltoid and triceps regions. Subsequent injections should not be given in the same spot as the preceding in order to avoid the possibility of a local reaction. Care should also be exercised that the injections are not given intravenously. The first injection consists of 1 cc. in each arm; 1.5 cc. being given in each arm at the second and third injections.

Sauer's experiences with reactions following these injections are as follows: "The local and systemic reactions are due to the vaccine (dead bacilli and endotoxin), and not to the phenol or medium proteins . . . Allergic reactions, sensitization to foreign protein and susceptibility to the Arthus phenomenon need not be feared, regardless of the amount of vaccine injected or the time interval between injections. . . . If a severe reaction follows an injection, the next injection may be postponed a few days, or only 1 cc. may be given (bilaterally) at subsequent injections and an extra one given a week after the third injection. The parents are forewarned of a transient rise in temperature, the temporary local reactions (redness, induration and tenderness) and the subcutaneous nodules, which may persist for a few weeks at the site of each injection."

Since the first three years of life constitute the danger period in whooping cough mortality, prophylactic vaccination should preferably be done during infancy. Sauer recommends that it be done during the second half of the first year of life. It would also be advisable to immunize older, nonimmune children who have some chronic or debilitating disease such as tuberculosis, asthma, chronic pulmonary suppuration, etc.

One extremely important point emphasized by Sauer is that whooping cough vaccine is of no value unless *it is given at least a month or longer before exposure. It is of no value*

if given after exposure or during the catarrhal stage and is of no therapeutic value at any time during the course of the disease. This, of course, is in keeping with the general immunological principles governing active immunization in any acute disease.

Sauer has published very convincing evidence, obtained from well-controlled studies, as to the effectiveness of whooping cough vaccine. In one of his studies he was able to vaccinate certain children in individual families and leave the others as controls. During the course of five years 31 of such control children in 24 families developed whooping cough, whereas; 29 vaccinated children in these same families who were intimately exposed during the incubation, catarrhal and paroxysmal stages, failed to develop the disease. During the same period 162 vaccinated children who were accidentally exposed failed to develop the disease. We have already quoted, in our discussion on etiology, the experiences of Macdonald and Macdonald, which are excellent evidence for the effectiveness of prophylactic vaccination. Recently, Sauer¹⁸ has described a few failures of his prophylactic vaccination.

During the past few years Krueger^{19, 20, 21} and his associates have described their method for the production of a so-called "pertussis" undenatured endo-antigen. We quote freely the description of their method. Phase I organisms are harvested in buffered, isotonic solution, thoroughly washed to remove metabolites and then mechanically disrupted by grinding for twelve hours in a special type of ball mill. The resultant suspension is subjected to ultrafiltration through acetic collodion membranes of such porosity that all intact cells are retained while material in solution or in a finely dispersed phase passes through. The *water-clear* filtrate contains those constituents of the live cell put into solution or suspension by physical rupture of the cell membrane. Each cubic centimeter contains the extract from 12 billion organisms.

We feel that there is insufficient evidence available to justify the assumption that this is a better immunizing agent than the vaccine prepared of whole organisms according to Sauer's method. Grinding will undoubtedly produce a suspension of smaller particles, however, the bulk of substance will probably be in physical suspension rather than in true chemical

solution. Under these circumstances the method of ultrafiltration which results in a "water-clear solution" will undoubtedly remove considerable immunizing substance. Furthermore, the method makes it difficult to quantitate dosage in terms of the amount of original substance. Recently an attempt has been made to standardize this product by nitrogen determinations. Krueger's main claim is that his antigen is "undenatured" because it has not been heated. We might point out again that Sauer's vaccine is *not heated*—in fact, it is subjected to much less physical manipulation than is Krueger's endo-antigen.

Miller²² has reported results in rabbits suggesting that Krueger's extract is better than other immunizing preparations. He determined this by means of complement fixation which, in our opinion, is not especially reliable for a quantitative study of the development of active immunity. Rabbits are poor animals for the study of such a problem since they are not susceptible to *Hemophilus pertussis* infection, or rather, they are naturally immune to it.

Frawley and his associates,²³ Stallings and Nichols,²⁴ and Munns and Aldrich²⁵ have reported results on the therapeutic use of Krueger's antigen in which they claim definite benefit from it. They do not seem to us to have proved this claim. In view of Sauer's experience that whooping cough vaccine is of no value in treating the disease (and this is the experience in other well-controlled observations) we see no reason why Krueger's antigen should have any therapeutic value at least insofar as such therapeutic value is dependent upon the development of an active immunity. Frawley²⁶ used this antigen prophylactically, and found that he did not get complete protection, although he states that the disease was milder. This experience, it seems to us, is further proof that this antigen is of no therapeutic value when given during the course of the disease. It is always difficult to appraise, even after careful questioning, the statements of a solicitous mother regarding the effect on her child of an "injection for his whooping cough." We feel that there is no justification for the use of any pertussis antigen or vaccine as a *therapeutic* agent.

In summary, it seems to us the evidence so far advanced indicates that whooping cough vaccine, as Sauer has prepared

it, represents a prophylactic *active immunizing* agent. We feel that its use is justified for this purpose only. Nevertheless, the experience with it is not yet sufficiently large to permit its acceptance without reservation or doubt. When it is used in a child the parents should be given no guarantee as to the result. It should not be forgotten that whooping cough is a protean disease and its contagiousness is not great compared to other communicable diseases. In fact, a considerable percentage of individuals reach adult life without contracting the disease.

Sauer's studies are still too recent to show how long the immunity will last following vaccination. It would appear that it will last longer than the danger period for pertussis mortality. Sauer has some children who have been exposed from five to eight years after vaccination without developing the disease.

PLACENTAL EXTRACT (McKHANN)

McKhann and his associates^{27, 28, 29, 30} have prepared an extract from human placentas which is capable of preventing or modifying measles in exposed, nonimmune children. That immune bodies might be derived from placentas and their blood content was suggested by the fact that: newborn infants are immune, for a period of several months, to certain communicable diseases: diphtheria antitoxin is present in essentially equivalent amounts in umbilical cord blood and in maternal blood. Furthermore, transplacental transfer of certain antibodies has been definitely shown to occur. This question of transplacental transmission has been reviewed in detail by McKhann and Chu in their first paper.

We quote McKhann's most recent technic for preparing placental extract, as follows: "Normal-appearing placentas from nonsyphilitic and nontoxic mothers were collected in lots containing from 8 to 50 placentas. The umbilical cords were tied to prevent loss of the fetal blood contained in the organs . . . the organs were ground very fine in a food chopper. Extraction was carried out with 4 per cent salt solution. Hypertonic saline was used in order to minimize hemolysis, which occurs rapidly in umbilical cord blood and in the placental extract prepared in isotonic salt solution. About

300 cc. of the salt solution was added for each placenta. The material was stirred mechanically for half an hour, and at the end of this time the tissue débris was removed by filtration through cheesecloth after which the blood cells were removed by centrifugation. Extraction of each lot was repeated once or twice so that the total amount of saline used was from 750 to 1000 cc. per placenta.

"Such extracts contained fetal blood, some maternal blood, and a quantity of placental tissue protein. Because of the association of immune bodies with the globulins of the blood serum of lower animals and presumably of human beings a concentrate of the active material and the removal of inert or noxious matter was sought by separation of the globulin fractions through precipitation with ammonium sulphate. Tests for toxicity and sex hormones indicated that the globulins contained a negligible amount of the hormones and that they were nontoxic for animals even if injected in large doses. Also, by animal tests and clinical trial the antibodies sought were found to be present in the globulin fractions."

Further differential precipitations were carried out at different concentrations of ammonium sulphate. The ammonium sulphate was removed by dialyzing in cellophane tubes against running water and isotonic salt solution. The material was preserved and sterilized by adding merthiolate 1:5000 or by passage through a Berkefeld filter.

In general it has been found that placental extracts are capable of: (1) neutralizing diphtheria toxin, (2) blanching a scarlet fever rash, (3) neutralizing poliomyelitis virus, and (4) preventing or modifying measles.

In their most recent paper McKhann, Green and Coady have presented the results obtained by studying the several protein fractions of placental extract as well as the total result of their experiences in the prevention and modification of measles with these substances. It was found that the substance neutralizing diphtheria toxin was found almost entirely in the pseudoglobulin fraction. The substance responsible for blanching scarlet fever rashes was also found almost exclusively in this same fraction. It was shown that injections of placental extract subcutaneously or intramuscularly in patients with a positive Dick reaction were followed by a period of

several days during which Dick tests were negative. This same observation was made independently by Ross.²¹

This striking protein distribution was not present in the case of antibodies for virus diseases, that is, for measles and poliomyelitis. In these instances the antibodies were distributed about equally between three fractions; the pseudoglobulin, the euglobulin and the tissue proteins.

These authors have presented data describing the use of placental extract for the prevention or modification of measles in 1285 nonimmune children. The several protein fractions were used. In one group of 560 children who were intimately exposed (under circumstances such that one would expect an infection rate of some 90 per cent) measles was either modified or prevented in 93 per cent.

With regard to reactions following the injection of placental extract in this large group of patients it was found . . . "that 23 per cent of the patients had mild local reactions and that 12 per cent had a slight general reaction as indicated by fever. The incidence of severe local reactions was 2.8 per cent and of more severe febrile reactions (indicated by an elevation of temperature over 101° F.), 1.9 per cent. In no instance did a local reaction persist longer than four days, and in no instance did suppuration occur." Reactions were more frequent among older children and adults than among infants and young children. Placental extract was found not to sensitize patients to subsequent injections of this material.

There appears to be no question but that placental extract is capable of preventing or modifying measles and should, therefore, be a valuable agent in the control of this disease. There is no reason to suppose that the activity of placental extract is due to substances different from those contained in convalescent serum. Its greatest merit would seem to be that an adequate supply of the material can always be available. It should do away with the trouble and annoyance of seeking and obtaining convalescent serum at just the right moment when occasion for its use arises.

As McKhann has pointed out, the immunity conferred by an injection of placental extract is passive and therefore of short duration. For this reason it is probably best not to use it for protection except in institutions and in debilitated,

tuberculous, acutely or chronically ill children. Its greatest value should be in its use as an agent to cause modified or mild measles. It is probable that under these circumstances permanent immunity against measles would result. McKhann has also pointed out that it is necessary to improve the product further to remove substances which might cause reactions and that some method of more certain and uniform standardization is very desirable. In the use of this extract it is most important that potent products, so prepared as to lessen the possibility of reactions, should be obtained.

TETANUS TOXOID

During the past few years tetanus toxoid has been developed and this product bids fair to supplant the older methods of prophylaxis against tetanus infection.

In 1924 and 1925 Ramon^{32, 33, 34} published his classical studies on rendering diphtheria toxin nontoxic by treating it for several weeks at 37° C. with 0.4 per cent formaldehyde. At about the same time Descomby³⁵ found that tetanus toxin could be rendered nontoxic by treating it in the same way. This product, toxoid, retained its antigenic properties in spite of the loss of toxicity, and thus offered a method for active immunization against tetanus.

Tetanus toxoid is prepared by the addition of 0.3 to 0.4 per cent formaldehyde to tetanus toxin and incubating the mixture at 37° C. for several weeks. The end-point of the period of incubation is determined by the loss of toxicity of the material for laboratory animals. By such treatment a toxin with an M.L.D. of 0.001 to 0.0001 cc. can be so reduced in toxicity that 10 cc. will fail to kill a guinea pig. Such toxins are considered to be adequately changed to toxoid when 5 cc. to 10 cc. fail to cause symptoms of tetanus when injected into a guinea pig. Bergey³⁶ and others have shown that the best toxoid is derived from the most potent original toxin.

There have been a number of studies on the production of antitoxin in human beings and animals following two or three injections of toxoid at biweekly or triweekly intervals. Such studies have been published by Ramon and Zoeller,^{37, 38} Sacquépée,³⁹ Lincoln and Greenwald,⁴⁰ Sneath,^{41, 42, 43} Bergey

and Etris^{44, 45, 46} and Bergey.³⁶ Ramon⁴⁷ has recently published a review of this entire subject. In general these studies have shown that the rise in antitoxin following the primary stimulus is rather slow, reaching a maximum in from three to five months. After this interval of time in persons receiving two or three injections of toxoid the antitoxin level in the serum averages about that occasioned by the injection of the usual prophylactic dose of antitoxin. However, in a large group of immunized individuals, there will be considerable variation in the level of antitoxin in their serum. This immunity apparently lasts for a considerable period of time. The serum antitoxin level apparently maintains itself for twelve to eighteen months and then slowly begins to fall. Ramon and Zoeller⁴⁸ injected a large group of individuals with tetanus toxoid and in some of them the serum antitoxin level following this varied from 0.5 to 1 unit per cc. Four years later 12 of these individuals had serum antitoxin contents of from $\frac{1}{500}$ to $\frac{1}{6}$ unit per cc.

It has also been shown that a secondary stimulus (an injection of toxoid in a person immunized some time previously) is followed by a very rapid rise in antitoxin to a new high level. Such a secondary stimulus is followed, in from seven to fifteen days, by a rise in antitoxin which may be several hundred times greater than the antitoxin level just prior to the secondary stimulus. In fact the level attained after such a stimulus is usually many times higher than the optimum level following the primary stimulus. The importance of this will be discussed later.

Recently, Bergey³⁶ has shown that tetanus toxoid can be precipitated with 2 per cent alum. When washed according to the method of Wells, Graham and Havens⁴⁹ this purified alum toxoid was not followed by the annoying reactions which sometimes followed the use of nonprecipitated toxoid. Because alum toxoid is retained longer in the tissues it acts as an antigenic stimulus for a much longer time than regular toxoid. A single dose of alum toxoid is followed by an antitoxin content similar to that following three injections of regular toxoid.

There is no question but that tetanus toxoid is an active immunizing agent and that it would seem to be perfectly

possible to immunize individuals against tetanus. However, it remains to be seen to what extent it will receive practical application. The incidence of the disease in the general population is sufficiently low to make it questionable whether large-scale immunization would be advisable. There is no question but that such immunization should be of great value in that portion of the population whose occupations make them special tetanus risks, *i. e.*, agriculturists and men engaged in animal husbandry and military campaigns.

In actively immunized individuals, even though the immunizing injections were given a considerable time previously, and their serum antitoxin may be very low at the moment, it should be possible to protect them against tetanus by administering another dose of toxoid at the time of an injury. We have already spoken of the rapid and marked rise in serum antitoxin following a secondary stimulus. Thus, when a previously immunized individual is injured he is given an injection of tetanus toxoid instead of tetanus antitoxin. Such a procedure, of course, avoids the development of serum sensitivity in such an individual. There will then be a sufficient rise in his own antitoxin level within the incubation period of the disease to protect him against tetanus. Furthermore, it is possible, in soldiers and others running a particular tetanus risk, to keep their serum antitoxin at an effective level at all times by giving a single injection of toxoid every twelve to eighteen months after they first have been immunized.

It should be pointed out and emphasized that tetanus toxoid is of no value as a therapeutic agent. It should never be given during the course of the disease. It is solely an active immunizing agent and should be used only for prophylaxis against the possible development of tetanus following a future injury. Furthermore, because of the slowness of antitoxin development following a primary stimulus it should never be used as a prophylactic agent at the time of an injury in a person who was not actively immunized previously.

It is regrettable that there is no simple test, analogous to the Shick and Dick tests, to determine susceptibility to tetanus. An estimation of the degree of protection in an individual can be determined only by measuring the amount of antitoxin in his serum. This is an elaborate procedure which

would not be practical in any large group of individuals. Without such a measurement it is impossible to know if an individual is adequately protected. This difficulty may prove to be a stumbling block in the way of large-scale immunization against tetanus. Uncertainty cannot be tolerated when one is taking care of an individual with a serious injury that is likely to be infected with tetanus bacilli.

Since tetanus toxoid is simply a detoxified filtrate of a broth culture of the tetanus bacillus, it is very likely that unpleasant reactions may occasionally follow its use, particularly in adults. This has been the case with diphtheria toxoid. It is possible, of course, to develop methods of purification which may eliminate some of these reactions. Bergey³⁰ has already shown that washed, alum-precipitated tetanus toxoid is less likely to cause reactions than plain toxoid.

Ramon⁴⁷ has suggested the use of a "triple vaccine." That is, a mixture of tetanus toxoid, diphtheria toxoid, and typhoid and paratyphoid A and B vaccine is given in a single injection. These injections are repeated at two to three week intervals for three doses. Ramon has shown that the immunizing activity of each constituent of such a mixture is just as good as when given separately. We feel that this program might be applicable to newly mobilized troops. However, one would question its value for use in the general population, in this country, at least. Typhoid vaccination is not done as a routine procedure in practice, and, as we have already pointed out, it is questionable if wide-scale immunization against tetanus should be practiced.

MENINGOCOCCUS ANTITOXIN (FERRY)

Ferry and his associates^{50, 51, 52, 53, 54, 55} have recently presented experimental data which they interpret as showing that the meningococcus produces a true soluble exotoxin against which a specific, neutralizing, antitoxin can be developed by the immunization of horses with this exotoxin.

The method employed for securing this exotoxin consists in cultivating the meningococcus in broth (Huntoon's hormone broth) for four to six days. The organisms grow in a heavy pellicle on the surface of the broth. After this period of incubation the broth is filtered through Berkefeld filters and

the resulting filtrate is said to contain an exotoxin. They have found that such filtrates contain a toxic substance specific for each of the four Gordon types of meningococcus and an additional toxic substance common to these four Gordon types.

These authors have shown that when their toxin is appropriately diluted in physiological salt solution it will, after its intracutaneous injection, cause a positive reaction, similar to the Dick reaction in a certain percentage of human beings. Individuals recovered from meningitis failed to give a positive skin reaction when injected intracutaneously with a toxin prepared from the same type of meningococcus as isolated from the patient. They claim that it was also possible to neutralize this reaction in susceptible individuals with the appropriate "antitoxin."

Ferry has immunized horses with his bouillon filtrates for the production of a meningococcus "antitoxin." The resulting serum has been used by him in a large number of animal protections and therapeutic experiments. Monkeys, rabbits and guinea pigs were used. Without reviewing in detail the numerous experimental protocols of this author, we may summarize by stating that Ferry has concluded from the data obtained that the meningococcus produces a soluble exotoxin and that a true antitoxin can be developed by immunization with this exotoxin.

In our opinion sufficient evidence has not been advanced to prove that the meningococcus produces a true, soluble exotoxin. It has long been known, of course, that the meningococcus produces a potent endotoxin. The reactions of this substance have been studied in great detail by Gordon⁵⁶ and by Murray.⁵⁷ Recently Malcolm and White⁵⁸ have published studies on meningococcus endotoxin. The reactions of animals to endotoxin, as described by Malcolm and White, are in no way different from those described by Ferry as being due to exotoxin.

The meningococcus is extremely susceptible to autolysis or self-digestion, which liberates intracellular toxic substances or endotoxin. This is particularly true when the organism is grown in a fluid medium. When the organism is grown in broth for four to six days there is abundant opportunity for the liberation of endotoxin by this autolytic process. There-

fore, immunization with such filtrates could result in the production of antiendotoxin. Such a serum need not be any different from the antibacterial sera produced by the usual methods of immunization with meningococci. We feel that Ferry's "antitoxin" is such a serum.

In Ferry's numerous protocols showing the protective and therapeutic effect of his "antitoxin" there is no evidence to show that it will neutralize in multiple proportions, which is a fundamental characteristic of true antitoxins. Furthermore, the effect of his serum, in the majority of instances, was studied in animals injected with living virulent meningococci, and there is no reason to believe that such effect was other than antibacterial. Furthermore, most laboratory animals, *i. e.*, rabbits and guinea pigs, are not truly susceptible to infection by the meningococcus.

An "antitoxin," moreover, could not be expected to rid the subarachnoid space of organisms, a result which is essential for cure of a patient with meningitis. No doubt such an antitoxin might relieve a patient of certain of his symptoms. On the other hand, there is no evidence that an antitoxin has any direct effect on bacterial cells. This has been abundantly demonstrated in the case of meningitis due to other organisms. For example, Dick antitoxin, regardless of the route of administration, does not alter the course of meningitis due to the scarlet fever variety of hemolytic streptococcus.

Hoyne⁵⁹ has recently published an analysis of a group of cases treated with Ferry's meningococcus "antitoxin." In this study 211 cases were treated with regular antimeningococcus serum and 85 cases were treated with "antitoxin." The mortality in the former group was 45.9 per cent, which is higher than that generally reported. The mortality in the antitoxin-treated group was 23.5 per cent, which is about the usual mortality rate given by others^{60, 61, 62, 63} for patients treated with regular antimeningococcus serum. Furthermore, this paper loses much of its statistical value because, as the author states, in 40 cases the clinical diagnosis was not verified by smear or cultures.

Banks,⁶⁴ in England, has used meningococcus antitoxin in a small series of cases. The mortality in this group was 28 per cent. He concludes that this mortality is no better than

the standard mortality rate given by Flexner for patients treated with regular antimeningococcus serum.

In conclusion we are not trying to show that Ferry's "antitoxin" is without value. We have endeavored to point out that, in our opinion, it is not different from the usual antimeningococcus serum and there is no reason for using it in preference to such products. We do object to its being used on the assumption that it is a true meningococcus "antitoxin." The evidence is not sufficient to justify its being so considered.

STAPHYLOCOCCUS TOXIN, ANTITOXIN, AND TOXOID

Staphylococcus toxoid and antitoxin are of direct interest to the clinician as possible therapeutic agents in certain types of staphylococcus infections. Before they can be discussed, however, it is necessary to review the properties of staphylococcus toxin. Toxic properties of the filtrates of staphylococcus cultures were first observed in the early days of bacteriology. The modern development of the subject will be reviewed below. Acute interest in the entire staphylococcus problem was revived by the Bundaberg accident. In this unfortunate episode 21 children were inoculated with a diphtheria toxin-antitoxin mixture that was contaminated with staphylococcus aureus. Twelve of these children died of acute staphylococcus septicemia within twenty-four to forty-eight hours. However these children did not die of toxemia, but of an acute, fulminating staphylococcemia. This was shown by Burnet⁶⁵ and by the Report of the Royal Commission,⁶⁶ which investigated it. It was shown that the toxin-antitoxin was heavily contaminated with living staphylococcus aureus and that little, if any, soluble toxin was present in the mixture. Burnet⁶⁵ showed that the conditions under which diphtheria toxin-antitoxin mixtures were prepared and kept, even though contaminated by toxicogenic staphylococci, were unfavorable for the development of toxin. We mention this because a few recent students of the problem, in reviewing this occurrence, have implied that staphylococcus toxin was the important factor in the death of the children.

The toxic principles in filtrates of staphylococcus cultures manifest themselves, under experimental conditions, in several

ways. The important manifestations are as follows: (1) Hemolytic activity. Potent filtrates, even in high dilution, will hemolyze a suspension of erythrocytes. Rabbit cells are generally used for such purposes. (2) Dermonecrotic activity. Such filtrates, even when considerably diluted, will cause an area of erythema with marked central necrosis when injected intradermally into rabbits and other animals. (3) Lethal effect. Such filtrates kill animals with extreme rapidity when injected intravenously. Rabbits die within one to three minutes following the injection of an appropriate dose. Dolman⁶⁷ has found other animals, including the guinea pig, horse, cat, and mouse, to be susceptible and subject to this rapidly lethal effect. It should be pointed out that this is an unusual property for a bacterial poison. Practically all other bacterial toxins require a definite incubation period of at least several hours before their action is apparent. The lethal effect of staphylococcus filtrates appears to be due to a direct action on the A-V bundle in the heart. (4) Leukocidin effect. Potent staphylococcus filtrates have a destructive action on leukocytes. The older literature concerning these properties of staphylococcus filtrates has been reviewed by a number of recent investigators, including Burnet,⁶⁵ Dolman⁶⁷ and Weld and Gunther.⁶⁸

That human beings are susceptible to the toxic principle in staphylococcus filtrates has been shown by a number of observations. In attempting to immunize patients with subcutaneous injections of small doses of toxin, Weiss⁶⁹ noticed that six to twelve hours after such injections there was often local redness and tenderness and occasionally swelling. He reported one instance where the injection of undiluted toxin was followed by intense inflammation and suppuration and with marked systemic symptoms. Pilot and Afremow⁷⁰ showed that the intradermal injection of diluted toxin in man caused a zone of erythema with swelling and tenderness within 24 hours. They were able to neutralize these reactions with immune horse and rabbit serum. Stevens⁷¹ reported 3 cases of acute staphylococcus aureus infection with a scarlatiniform rash. It was difficult to distinguish the rash in these cases from that in scarlet fever. The rash could be blanched with staphylococcus antitoxin.

In discussing the properties of staphylococcus toxin, especially its effect on man, mention should be made of another substance produced by certain strains of staphylococci which causes an acute gastro-enteritis. This substance has been found responsible for a number of outbreaks of so-called "food poisoning." Such outbreaks have been described and others reviewed by Jordan^{72, 73, 74, 75} and his associates. As has been shown by Dolman,⁷⁶ this "gastro-enteritis" principle is different from the toxin responsible for the effects enumerated above.

The production of potent staphylococcus toxin is dependent upon growing the organism under special cultural conditions as has been shown by Parker,⁷⁷ Dolman,⁶⁷ Burnet,⁶⁵ Parish and Clark,⁷⁸ Bigger,⁷⁹ Bigger, Boland and O'Meara⁸⁰ and Leonard and Holm.⁸¹ In general, the most potent toxins are obtained by growing the organism in a semisolid agar with a buffered broth or peptone base. Cultivation is carried out under an increased carbon dioxide tension. The amount of carbon dioxide used has varied from 10 to 80 per cent in the hands of different investigators. The toxin is easily destroyed in an alkaline reaction which makes it imperative to use a buffered medium. It is possible that the effect of carbon dioxide may depend entirely upon its buffering action. After forty-eight hours' incubation the inoculated semisolid agar mass is squeezed through cheesecloth. The resulting fluid is centrifuged and filtered through a Berkefeld candle. The reaction of the filtrate is adjusted to slightly acid; pH 6.8. Staphylococcus toxin is thermolabile, being destroyed by heating to 60° C. for five minutes.

There is, apparently, no correlation between the invasiveness of a particular staphylococcus strain and its ability to produce a potent toxin. Stevens and Carp⁸² studied 31 strains that were obtained from two sources. One group of strains was obtained from human lesions, such as furuncles, abscesses, and septicemias. The other group was obtained from the nasopharynx of normal individuals. The toxin produced by the various strains was apparently identical since the reaction of each toxin could be neutralized by the same antitoxic serum. There was no correlation between amounts and the properties of the toxins produced and the clinical origin of cultures.

With respect to the organisms isolated from acute infections there appeared to be no relationship between the severity of the infection and the ability of the corresponding strain to produce toxin.

There is considerable discussion in the literature as to whether the hemolytic, lethal, and dermonecrotic effects of staphylococcal filtrates are due to three different substances or whether these are different effects of a single toxic substance. On the basis of adsorption experiments Weld and Gunther⁶⁸ concluded that these different effects were due to different substances in the filtrates. On the other hand, nearly all other investigators subscribe to the view that a single toxin is responsible. Dolman⁶⁷ found that heating at 60° C. for different lengths of time caused the same relative effects on both the hemolytic and dermonecrotic titers. In studying the action of formalin on staphylococcus toxin Burnet⁶³ concluded that "all the characteristic activities of the toxin are lost concurrently in the process of formalin detoxication. In none of the experiments with partially detoxicated preparations has there appeared any indication that the three functions of the toxin, hemolytic, skin necrotic and lethal have been dissociated." Because there is practically complete agreement that the various manifestations of staphylococcus filtrates are due to a single toxin the Committee on Standards of the League of Nations⁶⁴ has provisionally adopted a method for standardizing staphylococcus antitoxin depending only on hemolytic activity. Separate assays dependent upon the dermonecrotic and lethal effects are not required.

All investigators are agreed that staphylococcus toxin is antigenic and that it is a true bacterial soluble exotoxin. The immunological reactions of this toxin and its antitoxin are, in general, the same as those which characterize true bacterial exotoxins as a class.

Staphylococcus toxin can be detoxified by formalin with great ease. After only a few hours' incubation in the presence of 0.3 per cent formaldehyde there is a marked reduction in its toxic action. After forty-eight hours' incubation it is practically completely atoxic. The toxoid is an effective immunizing agent.

Before reviewing the clinical use of staphylococcus toxoid

some consideration should be given to the question of natural antitoxin in man. This has been studied by a number of investigators, including Connor and McKie,⁸⁵ Ramon, Richon, and Descazeaux,^{86, 87} Bryce and Burnet,⁸⁸ and Murray.⁸⁹ In general the presence of "natural" staphylococcus antitoxin in man is somewhat similar in its distribution to that of diphtheria antitoxin. According to Murray and to Bryce and Burnet, umbilical cord blood and the blood of newborn infants contains antitoxin in practically the same amounts as in the maternal blood. This is gradually lost during early infancy. In later years there is a gradual rise in antitoxin to what is assumed to be a "normal" level. Expressing his values in terms of International units Murray found an average value of 0.78 units per cc. for the blood of newborn infants; 50 cases having been examined. In 50 pregnant women he found an average value of 0.75 units per cc. This investigator also found that the level of antitoxin in patients with chronic pyodermias of various kinds was not significantly different from his "normal" value. In 7 patients with osteomyelitis, however, the average value was 11.7 units per cc. Parish, O'Meara and Clark⁸⁹ report similar experiences.

During the past few years a number of investigators, particularly Parish, O'Meara and Clark,⁸⁹ Murray,⁹⁰ Ramon, Bocage, Richon and Mercier,⁹¹ Dolman^{92, 93} and Connor and McKie⁹⁴ have treated patients suffering from chronic staphylococcal infections with staphylococcus toxoid. Patients are usually given a series of subcutaneous injections at weekly intervals. The initial dose is small, *i. e.*, 0.05 to 0.1 cc. and is gradually increased at each subsequent injection. A series has usually consisted of 4 to 6 injections. In many instances such a series of injections has been repeated one or more times. It has been found that in the majority of patients there has been a gradual rise in antitoxin level to many times the titer at the beginning of treatment. Murray has made the interesting observation that there appears to be an optimum level to which antitoxin will rise following the administration of toxoid. Further injections will not increase it. It is interesting to note that this level is quantitatively similar to that naturally present in patients with osteomyelitis. He suggests that measuring the antitoxic titer in patients'

sera provides a reliable index for stopping treatment. There is no purpose in administering additional toxoid when the level above referred to has been reached.

It is generally agreed that a majority of patients with chronic pyodermias such as recurrent furunculosis, pustular acne, recurrent stytes, blepharitis, carbunculosis and other superficial abscesses and sycosis barbae are considerably improved by treatment with toxoid. A small percentage of patients are not helped. Kindel and Costello⁵⁵ were unable to observe favorable results in their patients. Their work has been criticized by Dolman on the ground that they used a toxoid produced by a single strain of staphylococcus rather than a pooled toxoid from several strains. We cannot agree with Dolman in this criticism. There is no evidence at the present time that there is more than one antigenic type of dermonecrotic toxin. For this reason there is no justification for using a pooled rather than a monovalent toxoid.

In reading the several reports concerning the clinical value of toxoid it is difficult to form an independent judgment concerning it. In most reports the cases have not been presented in a sufficiently objective manner to permit the reader to judge for himself. Murray's report is an exception. From his tables and the manner in which he studied his cases, it seems apparent that many of his patients with chronic skin infections were definitely benefited. It should always be remembered, of course, that it is very difficult to control the appraisal of the effectiveness of a therapeutic procedure in this type of infection. One can never know which crop of furuncles would have been the last in a given patient even if no treatment had been used.

With regard to osteomyelitis there is no convincing evidence that toxoid is of value. In this connection we might recall again Murray's observation that the antitoxin level in such patients is essentially equal to the optimum amount occasioned by a series of injections of toxoid.

In summary, it is our opinion that staphylococcus toxoid is a useful agent in the treatment of chronic staphylococcal skin infections. For this purpose a toxoid of known antigenic potency should be used. Injections should be given subcutaneously, starting with a relatively small dose, *i. e.*, 0.05

or 0.1 cc. The dose can be increased gradually at subsequent injections. One of two series of 4 to 6 doses each may be given. Five to seven days should elapse between injections. If results are not obtained after such a course of treatment there is no point in continuing it further. If possible, it is a good plan to determine the antihemolytic titer of patients' sera before and after such treatment.

In our opinion there is no convincing evidence at the moment that staphylococcus toxoid is of any value in infections other than the group of chronic pyodermias. In the present state of our knowledge we cannot advise its use in osteomyelitis and generalized pyemic infections. Furthermore, it definitely should not be used in acute and fulminating staphylococcal infections.

Considerable work has been done with staphylococcus antitoxin during the past few years, both in experimental animals and in human infections. Parker and Banzhaf⁹⁶ were among the first to produce in horses a staphylococcus antitoxin which was capable of neutralizing the dermonecrotic effect of the toxin. We are not aware of any reports of the use of this serum in human infections.

Burnet⁶⁵ in carefully controlled experiments in rabbits was unable to obtain convincing results in experimental infections with living organisms. When antitoxin was given intravenously immediately after an intravenous injection of living culture, the life of the animals was prolonged. This author was also able to demonstrate the production of staphylococcus toxin in vivo. In three rabbits dying acutely from staphylococcus septicemia the pericardial exudate contained a skin-reacting substance that could be neutralized by antitoxin. On the other hand, when rabbits were actively immunized by the subcutaneous injection of living cultures they failed to die acutely, but invariably died in from four to thirteen days from generalized pyemic infections. Parish and Clark⁷⁸ and Parish, O'Meara and Clark⁸⁹ found that life could be prolonged in rabbits passively immunized with antitoxin.

These experiments have considerable significance. They indicate that antitoxin may protect against acute death in staphylococcus septicemia and suggest that such acute deaths may be due to the in vivo production of toxin. However, it

does not protect against late death due to widespread pyemic lesions. This is to be expected, since the antitoxin has no bactericidal action whatever. Nor can antitoxin be expected to protect against the development of widespread pyemic lesions during the course of acute septicemia. A similar situation exists in other infections. For example, there is accumulating evidence that septic complications are not prevented in scarlet fever patients passively immunized with Dick antitoxin.

Several reports have appeared in which staphylococcus antitoxin was used in human infections. Panton, Valentine and Dix⁹⁷ report favorable results following its use in a small group of patients. Jamieson and Powell⁹⁸ are less enthusiastic in their use of antitoxin. While they do not give details of the patients in which antitoxin was used, they summarize their experiences as follows: "In staphylococcus pyogenic infections it has appeared that staphylococcus antinecrotizing serum has produced no uniformly good results. Vigorous intravenous and intramuscular antitoxin treatment in such cases extending over periods of from one or two to thirty days has sometimes had a favorable effect in reducing temperature and preventing daily chills, but blood cultures have in the main continued to be positive during serum treatment and metastatic infections have not been decreased or prevented. Local applications of staphylococcus antitoxin to abscesses have had a favorable effect in some cases; however, the efficacy of such treatment has not exceeded that commonly reported in the use of bacterial lysates." It is of interest to note the similarity of these results in human beings to those discussed above in experimental animals.

Dolman⁹⁹ has reported a large series of various types of staphylococcus infections and is an enthusiastic advocate of this form of therapy. However, because of the manner in which he reports his cases, it is difficult for the reader to form an independent appraisal of the results. At least his condensed mortality table is not convincing. Many of his cases received enormous doses of serum.

In summary, our own opinion, regarding the use of staphylococcus antitoxin is that it may relieve certain symptoms and may, in some cases of acute septicemia, prevent early death.

On the other hand, there is little reason to suppose it to have much curative value in subacute or chronic pyemia and osteomyelitis. Indeed, it might be said that antitoxin might change an acute, fulminating septicemia into the chronic type of pyemia with continuing positive blood cultures and developing pyemic abscesses. In the latter type of disease there is little to be expected from antitoxin treatment on the basis of existing evidence. It should be emphasized again that this antitoxin has no demonstrable bactericidal effect. We, therefore, feel that the therapeutic usefulness of staphylococcus antitoxin is limited.

CLINIC OF DR. JOE VINCENT MEIGS

FROM THE MASSACHUSETTS GENERAL HOSPITAL

RECENT ADVANCES IN MEDICAL GYNECOLOGY

THE purpose of this paper is to cover the recent advances in gynecology that are of value to medical men particularly. It is quite impossible to exclude certain advances that are of greater importance to surgeons and gynecologists. The subjects to be discussed cannot include all the advances but are selected by the author as necessary for the proper practice of medicine. Gynecology is so closely allied to medicine, endocrinology, physiology, pathology, and surgery that real gynecological knowledge should be all embracing. Under the last heading of this paper a short résumé concerning hormones, their commercial names, and a few explanatory diagrams will be found.

The present article is an attempt to classify the confusion of ideas as far as possible. It is clearly understood that many statements may prove to be incorrect later. If dogmatic statements are made they are made only to emphasize our knowledge as it is at the present time. Such a paper must be superficial and it is written only to aid practitioners who do not have the opportunity of working in research with the aid of well-equipped biological laboratories.

The subjects chosen to be discussed may be grouped under the headings—*inflammation, tumors, pathologic physiology, and endocrinology*. The necessity of giving credit where due in such a paper is not feasible and the author hopes that the lack of references to men responsible for outstanding pieces of work will be understood both by them and by their readers.

NEW DIAGNOSTIC METHODS

First to be considered should be advances in the methods of diagnosis. It is now clearly established that certain urine and blood tests for the presence or absence of pituitary or

ovarian hormones are of great value. Estrin¹ is present in the normal patient's urine and anterior pituitary prolan² is not. In the blood of the normal patient estrin can be detected and occasionally anterior pituitary prolan. In ovarian failure estrin should be absent and pituitary prolan present in both blood and urine, while in pituitary failure neither should be present in either. Blood tests are difficult to do but the urine tests are perfectly satisfactory so that the findings in the twenty-four hour specimen of urine and the morning specimen of urine are sufficient. Just before the menstrual flow the estrin content drops markedly and this fact should be taken into consideration when studies are made. Following removal of the uterus, if both ovaries are retained, the findings are just as in normal women. Removal of the uterus does not cause an early menopause if the ovaries are healthy and are left with an intact and satisfactory blood supply. The table below showing urinary findings has been used with considerable satisfaction in our Ovarian Dysfunction Clinic. Its absolute accuracy may be questioned, but as a working table its value is great.

	<i>Estrin.</i>	<i>Pituitary prolan.</i>
Normal.....	+	0
Ovarian deficiency.....	0	+
Pituitary deficiency.....	0	0
Pregnancy.....	+	+(pregnancy urine prolan)

After the test of a patient's urine has been reported, and more than one test should be made, the probable factor in the patient's difficulty should be manifest. For instance a patient with no estrin and positive prolan would be considered to have an ovarian deficiency.

Another valuable method of diagnosis is endometrial biopsy. This can be carried out in the office either with or

¹ As used by the author the term estrin includes all chemical types of estrogenic hormones.

² Anterior pituitary prolan is that substance from the anterior pituitary gland that brings about follicle formation, ovulation, and luteinization in the experimental animal ovary. It is recovered from the pituitary itself. Pregnancy urine prolan, or the so-called "anterior pituitary luteinizing hormone," is present in the urine of pregnant women and is that hormone that is responsible for the Aschheim-Zondek test and Friedman test. It has been on the market for some time under the various commercial names described in the section on hormones.

without a short anesthesia. The following methods are in vogue at the present time; the punch method, the suction curette method, and the small cup curette method. By means of the punch and small curette a piece of tissue can be removed from a given place in the endometrium while the suction curette removes much more tissue but the area from which it was removed is not so definite. If, as has recently been reported, we are to find different types of epithelium in different areas of endometrium perhaps the suction method is best, as it removes more than one piece. The value of the biopsy lies in the fact that the pathologist should be able to tell whether or not a given patient has ovulated. The so-called "premenstrual, progestational, or secretory phase" does not occur without ovulation. Therefore if a specimen is removed about the twentieth to twenty-fifth day after onset of a menstrual period secretion should be present, if it does not show secretion the patient may not be ovulating and therefore her flow comes from a proliferative or estrin phase and not from the corpus luteum or secretory phase. This fact might account for her menstrual abnormality or sterility. This simple test has been of immense value in determining late ovulation, early ovulation and anovulation and gives accurate evidence of the results of hormone treatment.

The measurement of the uterus is an important aid in investigation of the gynecologic patient. This is done with an instrument devised by Samuel Meaker and consists of an ordinary uterine probe marked in centimeters and a collar that can be moved up and down the shaft to allow readings of the length of the cervix from the external to the internal os and the length of the uterine canal from the external os to the top of the fundus. The normal measurements of the whole uterus to the cervix should be in the proportion of three to one; in the juvenile uterus it is as two to one, and in the infantile with its long conical cervix as one to three. These measurements are easy to obtain and may be the clue to the reasons for amenorrhea, dysmenorrhea, sterility, etc.

Congenital erosion of the cervix has been observed in both anatomical and function disturbances of the genital tract. The name is not a true descriptive term for the condition is not a true erosion but a maldevelopment of the cervix. The circular

strawberry-red area surrounding the external os of the virgin cervix is made up of endocervical glands and is a stigma of hypoplasia. The uterus is not normally developed if the endocervical glandular epithelium is not properly drawn up into the cervical canal. The "erosion" is the exposed endocervical epithelium. Unquestionably this type of cervix tells a story of underdevelopment and many instances have been seen in our clinic that prove the importance of the consideration of this lesion in proving hypoplasia. It is a stigma of lack of normal development and should be carefully watched for.

Molimina or premenstrual feelings, probably due to increasing estrin production, are of importance. The normal woman can usually tell when her next period is due by the "feelings" of depression, easy weeping, backache, bloating, bearing-down, painful breasts, pimples, cramps, and whitish discharge. Many other sensations are noticed but the above are the most common. If a patient with amenorrhea has such rhythmic feelings it is certainly a sign of ovarian function for with the ovaries removed these feelings vanish. With the ovaries present and the uterus out molimina are still present. Such "feelings" may give a clue to the proper time to start treatment in the amenorrheic patient and the dates of such occurrences are of considerable worth. A lack of molimina in the amenorrheic patient may indicate a primary ovarian dysfunction and in a patient such information would be of enormous value.

Hirsutism, or abnormal growth of hair, is a common finding in our clinic and is difficult to evaluate. Without doubt certain women have more masculine characteristics in their make-up than others, just as certain men have more femininity than others. Also certain races tend to moustaches and beards and hairy arms, while others do not. If the hirsutism has been present since youth its significance is not so great as when it suddenly appears. The recent onset of hirsutism in a woman may mean nothing serious or it may mean the onset of a masculinizing process due to pituitary disease (basophilism), adrenal cortex disease, or a masculinizing tumor of the ovary (arrhenoblastoma). Certainly such evidence is of importance.

In another field altogether are two investigative methods that are proving of more and more importance. Most of us

cannot interpret the findings correctly as yet but practice will prevent serious lesions from developing under our observation. Cancer of the cervix, next to cancer of the breast, is the most common lesion of malignant neoplastic nature that woman has. If earlier diagnosis is possible then we must all familiarize ourselves with the method. Schiller found that iodine in the form of Lugol's solution, if applied to the normal healthy cervix, stained it a dark brown. He found that it stained scars, erosions of the cervix, and chronic inflammatory processes a lighter shade of brown but he also found that Lugol's solution did not stain leukoplakia or early cancer of the cervix at all. This lack of staining is due to lack of normal glycogen content of the cervical epithelium. Therefore, with a vaginal speculum and a nasal spray full of Lugol's solution, with the cervix gently wiped dry with cotton, a very important observation can be made by any one. If on such an examination a white patch of any size is discovered the patient should be investigated further. The piece of tissue should be examined microscopically to determine the type of lesion, and if leukoplakia the offending area or cervix should be removed, and if cancer the uterus should be removed or radium applied, depending upon the advice of the surgeon or gynecologist. Hinselmann has developed the colposcope (vagina scope) to a high degree of usefulness and his writings and the writings of others clearly describe the appearance of leukoplakia, premalignant or malignant conditions of the cervix. This instrument magnifies the cervical epithelium ten times and makes the observation of small areas of atypical epithelium easy. Without doubt small areas may be seen that cannot be detected with the naked eye and large areas of abnormal tissue may be studied more carefully. Mucous secretory ducts, Nabothian cysts, irregularities in the smooth epithelium, and leukoplakia are easy to detect. Not all can own such an instrument, but there is no doubt about its value and its usefulness.

INFLAMMATION

Advance has been made in the interpretation of vaginal discharges. The most important is the recognition of the *Trichomonas*. This flagellate is frequently found in women

without symptoms but more often it is the cause of an irritating, odorous, profuse, white to yellow discharge. The patients frequently complain of a disagreeable feeling and irritation of the vulva and inside of the legs. Recognition is easy. A drop of discharge is placed on a glass slide with a drop or two of warm water added and covered with a cover slip. The high dry power of the microscope is used. The light is cut well down and structures the size and shape of pus cells can easily be seen jerking their way in the moist smear. They may be confused with phagocytic cells, but if watched carefully small whips can be seen at the periphery of the cell. The complete configuration of the trichomonas is rarely seen. These organisms are most often part of a mixed infection so that pus and bacteria are commonly present.

The treatment is not easy. Many cases are encountered but few cured. The variety of the methods of treatment show that there is no specific one. It is very important to instruct the patient to wash the vulva and perineum carefully after each defecation; she must also be instructed to wipe the anus from front to back and not back to front. In the office the vagina should be gently cleaned out with dry cotton or cotton soaked in green soap and water. Then the treatment can be applied. The vagina may be painted with pure pyroligneous acid and soft tampons covered with Lassar's paste inserted to balloon out the vagina. The tampons are removed in forty-eight hours and douches of one teaspoonful of a 1: 100 solution oxycyanide of mercury to one quart of water are used daily. Another treatment after cleaning of the vagina is to use picric acid vaginal suppositories 1 grain each night, washing out the suppository each morning with a douche of sodium perborate, one teaspoonful to one quart of warm water. The patient should be warned to wear her menstrual gear at night, as the picric acid stains the night clothes. Stovarsal powder in a powder blower used two to three times a week in the office frequently clears the condition. Recently Devegan tablets (Winthrop Co.) have proved effective. Two tablets are placed high in the vagina at night and are douched out in the morning with one teaspoonful of sodium perborate in one quart of warm water. The treatment continues till tablets and douches are no longer necessary.

All of the above treatments make the patient comfortable, but do not guarantee that the infection will not return if the treatment is neglected or given up. Cures sometimes seem easy but recurrences are easier. There is no one method of absolute cure.

Monilia infections are of a similar sort and cause a vaginitis with a more watery discharge occasionally with white pieces of tissue in it. The diagnosis is made by staining some discharge on a slide with Gram's stain and looking for yeasts and long branching mycelia. The treatment is cleanliness, careful wiping of the vagina and the use of alkaline solutions, such as mild sodium bicarbonate douches, and glycerin and borated sodium bicarbonate suppositories. The use of 1 per cent aqueous solution of gentian violet painted over the vagina is of considerable value.

Much has been written of the treatment of vulvovaginitis of gonorrheal origin in children. This infection is very persistent and resistant but the knowledge of the ability of estrin to change the infantile vaginal mucosa to adult squamous epithelium is the basis of a new treatment. Five hundred international units of estrin by mouth daily will suffice to change the epithelium. When the epithelium becomes adult in type the gonococcus is supposed to remain no longer as an inhabitant of the vagina. There is no doubt that this form of treatment will change the lining of the vagina. Although relief of symptoms is early and easy and the vaginal changes can be watched by vaginal smears under the microscope, nevertheless the cure of this condition by this method is not always accomplished. Certainly it is a step forward and no untoward reactions have been seen in the children. Occasionally, if the dose is too large, the patient will complain of swelling in the breasts, and in one case a moderate amount of vaginal bleeding ensued.

The treatment of pruritus vulvae is still difficult. Absolute cleanliness, the use of carbolic acid lotions and other mild analgesics are helpful, but if the pruritus is persistent and the discomfort of the patient extreme, alcohol injection under an anesthetic may be tried. If one to 2 drops of 95 per cent alcohol are injected $\frac{1}{4}$ to $\frac{1}{2}$ inch apart at the periphery of the area of pruritus relief can be obtained in some of these

very difficult cases. The vulva may swell after the treatment and remain painful for a few days. Not over 10–20 cc. of this solution should be used at one time.

It should not be forgotten that diabetics frequently have itching of the vulva and a urine analysis must always be done. Many cases of pruritus are due to epidermophytosis and eradication of this infection is frequently followed by relief. The use of mild salicylic acid and benzoic acid preparations, the strength depending upon the amount of cracking and fissuring of the skin, is advocated. Cleanliness, and avoidance of scratching are important factors in the cure.

The severe itching and discomfort of leukoplakic vulvitis and kraurosis vulvae are best handled by radical excision of the vulva. Both lesions are precancerous and radical surgery cannot be criticized. Section of nerves crossing the perineum is advocated but often falls far short of cure and if operation is to be done vulvectomy with removal of diseased tissue is probably safest.

TUMORS

Tumors of endocrine significance are not uncommon but recognition of them has only been recent. Certain of these tumors are accompanied by subnormal development of the host, others cause masculinization and still others, femininization. The knowledge of the existence of such tumors is important and if a patient with certain peculiar characteristics has an unusual tumor the cause and effect may be evident. The ovariotesis or combination testicle and ovary is rare, and is often accompanied by hypospadias. The testicular tubular adenoma of Pick is a type of arrhenoblastoma (arrhenos meaning male) and may cause mild masculinization and failure of the ovaries and removal allows femininity to redevelop. The suprarenal hypernephroma either of the suprarenal gland itself or of the ovary causes a severe masculinization. In cases of masculinization of recent development such lesions must be looked for. In basophilic adenoma of the pituitary (Cushing's syndrome) amenorrhea and masculinization with marked hirsutism are not uncommon. The disgerminoma or seminoma of the ovary may be accompanied by a neutral development of the patient, the sex organs being rudimentary or with only partial develop-

ment. Femininizing tumors are of the granulosal, lutein or thecal types and are accompanied by the secretion of estrin and by menorrhagia before the menopause and abnormal bleeding and resumption of periods after the menopause. The granulosal cell tumor is more frequently malignant than benign. Its removal with removal of its estrin secretion allows the patient to return to normal. The luteoma, a rare tumor, is probably a granulosal cell tumor that has changed, as it physiologically could, into a tumor of luteinized granulosal cells. The existence of luteoma is often questioned. These various neoplasms must be borne in mind for neglect or ignorance of them might result in a disaster for their malignancy, excepting the first two, cannot be underestimated.

OVULATION

Much work has been done in attempts to establish the time of ovulation. If ovulation time were accurately known the treatment of sterility would be aided and the prevention of conception made easier. The ovum is supposed to live but twenty-four hours and the spermatozoön for three days, therefore if the time of ovulation were accurately established this time could be avoided for four days as a method of contraception or be used to aid in conception. The consensus of opinion seems to be that ovulation takes place from the twelfth to the seventeenth day after the onset of the menstrual period. Therefore from the ninth to eighteenth days after the onset of the catamenia is either the time to avoid or to indulge in intercourse, depending upon the result desired. Some patients can easily determine the exact time of their ovulation for they notice a sensation of gas or discomfort in the abdomen at the midmenstrual point. This happening is probably due to ovulation and if the pain or symptoms are exaggerated the patient is frequently operated upon for appendicitis and a normal appendix removed. Careful inspection of the ovaries at the operation would disclose the fact that a follicle had just ruptured and coagulum and blood would be found in the pelvis. Certain other patients notice a regularly occurring midmenstrual flow or pink discharge which is due to bleeding probably by diapedesis from an endometrium congested at the time of ovulation. Because of the drop in estrin that

occurs at this time bleeding occurs. Careful questioning of the patient regarding every possible factor in the menstrual cycle often proves of great value.

Operations in young girls for chronic appendicitis are often due to ignorance of the physiology of the ovary. Lack of a proper exploration of the patient's pelvis fails to reveal the true reason for the pain. Girls with mild pain at the intermenstrual point can be carefully watched and if no untoward symptoms develop surgery can be avoided. This at least is an important outcome of our more enlightened knowledge of normal ovarian physiology.

SEX DETERMINATION

Although many have searched for a means of determining the sex of the unborn child no discovery of importance has as yet been verified. Certain suggestive findings have been reported but none that has proved satisfactory. Studies of the blood and urine to determine the presence or absence of estrin to prove the sex in cases of hermaphroditism and patients without vaginas have no value. It is not possible to establish the proper sex by hormone determination.

FRIGIDITY

To relieve frigidity in the female has frequently been the goal of medical men and gynecologists. The problem has not been satisfactorily answered as yet but certain investigators while giving patients huge (100,000 to 200,000 I. U.) doses of estrin to bring about menstruation in the amenorrheic have noted increase in libido during treatment. This opens a field for speculation and the use of estrin may prove of value in some cases. It is just as sure, however, that in other cases it will be of no value whatsoever. Smaller doses may be tried for the expense of huge doses of this hormone is too great for most to bear. The reaction of patients after the menopause is of interest—some patients are completely frigid, some have a greater libido, and some are unchanged. Perhaps it is lack of estrin that determines the problem, but there is no definite proof as yet, although estrin has aided frigidity in certain cases. Some patients after x-ray treatment given to destroy the ovaries, note an increase in libido for a short time and after

a few months a great loss of feeling. Unquestionably all patients who are to have x-ray treatment over the pelvis should be warned of the possibility.

Careful and thoughtful psychological examination is the most useful method of investigation and sympathetic history taking may unravel an unexpected situation. Certainly dyspareunia or painful coitis makes for frigidity and if this can be cleared up frigidity may vanish.

STERILITY

The study of sterility and fertility is fascinating and the number of investigators enormous. There are certain facts that seem important and are rather new. The anovulatory cycle is of paramount importance—though suspected as a possibility for years, only lately has the fact been established. Many women flow irregularly and a few absolutely regularly without having a graafian follicle rupture. Of course if ovulation does not occur no woman can conceive. To establish the presence of ovulation it is necessary to curette the endometrium or do an endometrial biopsy. This should be done on about the twenty-fifth day after the onset of menstruation. If such a piece of tissue shows only a proliferative or estrin phase and no premenstrual or secretory phase and the patient flows shortly afterward she can be considered as going through an anovulatory cycle. There is no absolute cure for such a condition and before any treatment is instituted the test should be repeated, for it has frequently been noted that after such a curettage or biopsy the patient has become pregnant. It has also been noted that after an endometrial biopsy the next biopsy shows a premenstrual or secretory phase. These facts probably explain the frequent occurrence of pregnancy following dilatation and curettage, following the Rubin test, and following lipiodol injection of the uterus to determine the patency of the tubes. Trauma of the cervix or the uterus may be the responsible factor (just as in the rabbit, ovulation does not occur without copulation). Trauma followed by ovulation, no period and conception—this sequence of events has occurred so frequently that the probability is perhaps a fact. Another method of inducing ovulation is to use one of the anterior pituitary sex hormones (not

pregnancy urine prolan, the anterior pituitary-like hormone) in an endeavor to stimulate follicle formation. It is not certain that it always occurs and that if it does that ovulation takes place, but it should be a more satisfactory method of treatment than the use of prolan from the urine of pregnant women. The use of pregnancy urine prolan in sterility work is fraught with danger, for many investigators feel that this substance causes changes in the ovary suggestive of atresia, the opposite effect to the desired one. Estrin, as it does nothing to the ovary and as it is supposed to inhibit the action of the pituitary, should not be used. Yet certain men interested in sterility work have no hesitancy in reporting its success occasionally, but the explanation is not known.

Certainly in sterility cases the measurement of the uterus is important. Many a uterus that feels large on examination is really infantile or juvenile in structure and although a patient with this type of uterus may become pregnant, nevertheless in a sterility case knowledge of the hypoplasia is of great importance.

Thyroid is an important agent in treating sterility patients and many have conceived after taking small amounts ($\frac{1}{2}$ grain daily) for short periods of time. In patients with low metabolisms this is of great importance, but even in those patients with normal metabolisms treatment with thyroid has proved of value.

A factor frequently overlooked but of great significance is the condition of the ovum or spermatozoon. The so-called "blighted" ovum is due to a defective ovum or sperm and it is very possible that defective germs are produced because of an intrinsic fault in a patient's gonads. The production of such a defective ovum may allow menstruation in all its phases to take place but completed pregnancy may never occur.

Habitual abortion is not actually a problem of sterility, yet the patient who aborts is sterile as far as a living child is concerned. The problem here is perhaps overactivity of the estrin-primed uterus due to lack of the quieting corpus luteum hormone, progesterin. The first endeavor to treat this condition was the attempt to create an effective corpus luteum in the ovary by using pregnancy urine prolan to stimulate luteinization. Now that we suspect that this hormone (preg-

nancy urine prolan) does not cause luteinization it is not wise to use it. Progesterin is now on the market under the trade names of Corlutin and Proluton. This substance, if potent, should be able to quiet the estrin-irritated uterus and in some cases it has done so, preventing habitual abortion and allowing pregnancy to proceed to its conclusion. The dosage should be $\frac{1}{10}$ to 1 rabbit unit two to three times per week.

Apparently vitamin E is important in patients who abort habitually. It has been shown that lack of vitamin E causes death in utero. This vitamin is easily available in lettuce and in wheat germ oil. The latter is now on the market and 5 to 10 drops daily is a sufficient dose.

THE BREAST

The breast is acted upon by estrin and progesterin. Estrin acts upon the duct system and progesterin upon the alveoli. After the breast has been properly primed by these two hormones during pregnancy prolactin (from the anterior pituitary) acts upon it and causes lactation. Lactation has not been produced in castrated women by this method but marked and suggestive changes have occurred in the breast.

The premenstrual painful breast may be due to overstimulation by estrin. To relieve the pain and discomfort it is necessary to diminish such secretion. One method would be x-ray treatment of the ovaries or destruction of the pituitary secretion that stimulates the ovaries. Obviously these are not the proper methods, therefore, inasmuch as we believe excess of estrin will inhibit the pituitary gland estrin should be used before the oncoming period and omitted about five days before it is due. Thus the pituitary would cease secreting and in the remaining five days before the oncoming period would not have time enough to produce more estrin from the ovary. Therefore the estrin content would be reduced and consequently less pain occur in the breast. This theory is not without its defects but surprisingly enough the treatment is effective in many cases. Six hundred international units of estrin given daily except for the five days before the oncoming period has proved effective.

Another condition in which to use our knowledge of breast physiology is in the breast that lactates after cessation of

nursing or the breast that lactates and swells at the time of weaning. Prolactin (an anterior pituitary hormone) will not act in the presence of estrin, therefore large doses of estrin should stop lactation. It has been found that if live pieces of chorion are left in the uterus after delivery lactation is prevented. This is because the chorionic tissue secretes estrin, which prevents the action of prolactin.

It is conceivable that chronic cystic mastitis, a disease more frequent in the unmarried woman with unused breasts, may be due to constant stimulation of the duct epithelium by estrin with no letup of this stimulation such as occurs in pregnancy and lactation.

Treatment of the bleeding nipple by means of estrin has been advocated by Mazer, who believes that excessive anterior pituitary lobe hormone causes an abnormal response of the alveolar system. He believes that this type of mazoplasia may be accompanied by papillary growth in the upper ducts and is due to lack of estrin as well as increase of anterior pituitary hormone. The treatment should be inhibition of the pituitary by more estrin and he has found that this treatment is satisfactory to check pain and stop bleeding. That there is danger in such a method of treatment is unquestionable, for bleeding from the nipple may be due to a papilloma and this papilloma may be a serious one and not a benign one. Also certain cancers of the breast are accompanied by bleeding and differentiation between the two is difficult.

One of the most satisfactory forms of treatment of breast discomfort is the use of a proper supporting, as contrasted to pressure, brassiere. This simple expedient is frequently overlooked and its importance cannot be overestimated.

PREGNANCY TESTS

The Aschheim-Zondek and Friedman tests are from 90-98 per cent perfect. Most of the failures have a real explanation and some negative results are proven positive upon a repeat test. It is not wise to conclude that a patient is not pregnant if signs point toward pregnancy till at least two tests have been completed. False positives are often due to different types of female sex dysfunctions.

The use of pregnancy tests to diagnose extra-uterine preg-

nancy has not met with universal agreement. The Friedman or rabbit test should be used because of its quickness. If an extra-uterine pregnancy is suspected and the patient is in excellent condition and not bleeding, the test should be done. but if the patient is ill and there is an abdominal emergency. operation is the proper treatment and an attempt at too fine a diagnosis might prove disastrous. The test should be positive as long as any living chorion is present in the tube or abdomen.

The Aschheim-Zondek or Friedman test should be negative seven days after termination of pregnancy. The presence of living chorionic tissue will continue to give a positive reaction. If such a reaction persists the question of retained products or of chorionepithelioma should be raised. High titers of ten to fifty times the usual amount of prolan should be considered as a serious finding. In hydatid mole the test is high and in chorionepithelioma very high. If after a mole, chorionepithelioma, or pregnancy, a test that has been negative becomes positive a very serious condition has probably arisen, either tumor has developed or recurred or a metastasis taken place. If the test persists after miscarriage, pregnancy, or mole a curettage should be done and if it is positive after this a diagnosis of possible tumor must be made and hysterectomy is justified. If the test persists after the hysterectomy then it is probable that a metastasis has taken place.

Certain teratomas of the ovary containing chorionepithelioma give positive tests, and the finding of a tumor in the pelvis not a pregnancy with a positive test should make one suspicious of this type of lesion.

AMENORRHEA AND DELAYED MENSTRUATION

Amenorrhea is an expression of absent ovarian function. If primary, its cause lies in the ovary itself, and if secondary, in some outside influence that affects the ovary. In the treatment of such a condition it is necessary to know the type of amenorrhea the patient suffers. A study of the hormones present in the urine helps. If estrin is absent from the urine and prolan is present, the ovary is primarily at fault. If, however, prolan (from the pituitary) is also absent the ovary may be able to function but stimulation of it is absent. Endometrial biopsy will also indicate whether the ovary is

going through any sort of cycle or whether it has ceased to function. There is no doubt but that influences other than the pituitary may be at work. For instance, in hyperthyroid states or myxedema, the ovary often ceases to function. Any debilitating disease such as tuberculosis, allows the functions least necessary to life to cease. As the reproductive function is the least necessary for carrying on life, it is early affected in disease. Once the reason for the amenorrhea is established intelligent treatment can be carried out. If the cause is prolonged illness it can be treated with hope of cure. If pituitary dysfunction is responsible, then the hormone of the anterior pituitary should be tried. Doses of Prephysin (Chappel) from 25 to 200 units should stimulate the follicles of the perfectly good ovary and ovulation may follow. The use of this extract has certain dangers as overstimulation of all follicles might result. It is conceivable that too many of the follicles might be stimulated and this might have serious consequences. If the ovary itself is at fault the stimulation with pituitary hormone is again advised though the result may be unsuccessful, for if the ovary is too far atrophied then no stimulation will revive it. Such treatment is, however, perfectly justifiable.

Estrin and progestin can be used to bring about a menstrual period but as ovulation does not occur in such instances its value can only be psychic and the expense of the large doses necessary (100,000 to 200,000 international units of estrin and 10 to 50 rabbit units of progestin) are prohibitive. It is possible that such a treatment by bringing about a menstrual cycle might cause it to continue, but there is no reason for expecting such a result.

It has frequently been noted that patients with thyroid underfunctions are amenorrheic and the wise use of this extract has proved of value in many instances. Thyroid is of real value in amenorrhea and should always be tried, but the basal metabolism should be used in conjunction with it.

Estrin itself may cause the endometrium to develop and proliferate and when withdrawn may allow bleeding to occur. This bleeding is bleeding from the proliferative type of endometrium only as no secretory change can be brought about by estrin alone. Ovulation has not occurred. Psychologically

this bleeding may be of value to the patient but it is not a physiologically perfect result.

The amenorrhea of obesity and certain functional disturbances as well as those due to wasting disease are the ones most likely to respond to treatment. Real deficiencies such as pituitary or ovarian are much less likely to respond.

There are types of temporary amenorrhea associated with follicular cysts of the ovary that can be treated either by means of surgery (excision or puncture of the cyst) or even rupture of the cyst by bimanual examination, though this latter type of treatment is not recommended.

The use of estrin to develop a small uterus, especially when the uterus is considered the organ at fault, has its advocates and if large doses (1000 to 3000 I. U. of estrin) are used daily over monthly intervals, it is conceivable that such an effect could be brought about.

Amenorrhea should not be allowed to continue untreated in girls of child-bearing age, because if the delay in the catamenia is allowed to progress beyond a year, cure of the condition is very unlikely. Prompt treatment of the undernourished, sick, and underdeveloped, and the use of thyroid and pituitary hormones should be instituted early in the dysfunction if results are to be obtained. The same treatment should be accorded those individuals who have a delayed onset of periods (menarche) and great industry should be employed to bring about the onset of flow. If a girl has not had a period at the age of sixteen then treatment should be undertaken. Proper hygiene, endometrial biopsy, anterior pituitary prolan, thyroid, etc., should be employed early.

Certain anemias of youth are often accompanied by amenorrhea and such blood dyscrasias should be investigated and the anemia corrected. A secondary anemia of the chlorotic type may be responsible and the response of the dysfunction following treatment of the anemia with iron is often striking.

Cysts of the corpus luteum with a persistent secretory phase and decidual formation in the endometrium are possible and although cases have been reported in the literature they are not common. Such pathology should, however, be searched for and if found, the cyst should be excised.

DYSMENORRHEA

The study of dysmenorrhea is far from finished and the problem is so great that only the barest outline of procedure and treatment can be outlined. Dysmenorrhea occasionally responds to psychotherapy, to medical treatment, to hormone therapy, and to surgery. Many are the tools of the profession in the treatment of the condition but few the complete cures.

Pelvic examination in patients with dysmenorrhea may disclose a small, underdeveloped, anteflexed or retroflexed uterus, or a small-sized uterus in normal position or retroversion, or a large boggy uterus in retroversion, or even a normal-sized uterus in good position. Pelvic inflammations, intramural or submucous fibroids may also be possible causes and must be borne in mind.

The typical uterus of the patient with dysmenorrhea is either ante or retroflexed and is usually of smaller rather than larger development. Measurement of the uterus if the hymen is ruptured, may give a clue to the proper treatment, for if it is underdeveloped attempts at further development should be carried out.

That psychic disturbances are causal factors cannot be denied but often after careful investigation with mental relief to the patient dysmenorrhea continues. Without doubt dysmenorrhea may be made much worse by an over-solicitous mother and over anxiety at the time of the catamenia is an undoubted factor. However, such patients may have dysmenorrhea after marriage when away from maternal solicitude and not be relieved till after the birth of a child. There is a goodly percentage of cases in which dysmenorrhea recurs after childbirth, to the consternation of the doctor, who said that childbirth would cure it. There is no absolute cure except hysterectomy and this should not be considered until the very last resort.

The first treatment should be carried out by the family doctor, who should try to correct any worries that the patient may have and he should warn the anxious parent against pitying the child too much. The health of the patient should be noted and any sign of underdevelopment or undernourishment corrected as far as possible. If the uterus, on rectal

examination, is found to be flexed forward or back and of small size, then the use of estrin is indicated. Whether or not growth actually occurs is not altogether settled but it is theoretically sound and worth trying.

The inhibiting action of estrin is another reason for its use and certain cases are much relieved by giving subcutaneously 50,000 I. U. seven days before the onset of the coming period in one dose. Estrin, when used in this fashion, is supposed to inhibit the pituitary gland from secreting prolactin A that in turn causes secretion of estrin in the ovary. If we believe that estrin sensitizes the uterine musculature, which it probably does, then we can lower the amount of estrin present at the time of menstruation by the above method. By giving a large dose before the oncoming flow we prevent the pituitary from causing the ovary to secrete more estrin and in the seven days left before the period is due there will not be time to manufacture more and the estrin given subcutaneously will have been used up. Thus at the time of onset of the catamenia the estrin content should be low and the uterus not as sensitive. This method has been successful many times and its use is advocated. The reasoning for its use may not be correct but the results obtained justify the therapy.

It is known that the hormone of the corpus luteum, progesterone, causes a cessation of motion in the uterine musculature brought about by estrin. It would seem logical, therefore, to use progesterone to quiet the sensitized uterine musculature and thus cause a cessation of cramps. This should be a valuable method of treatment now that progesterone is available for use. The dosage should be as large as the individual patient can afford and from 1 to 50 rabbit units could not be too great a dose.

The above method has been tried before but in a different way. Pregnancy urine prolactin was supposed to cause luteinization and thus bring about a secretion of progesterone *but* until it is more definitely settled that pregnancy urine prolactin does affect the ovary and how it does its use is theoretical only. The consensus of opinion now seems to be that pregnancy urine prolactin produces atresia in the ovary and that although theca luteinization may occur real luteinization does not. That these observations are correct is another question and only

further study will prove them. Certainly the effects of pregnancy urine prolan on the ovaries of mice and the presence of lutein cysts of the ovary in hydatid mole and chorionepithelioma (when the urine contains immense quantities of pregnancy urine prolan) makes it difficult to doubt the luteinizing power of pregnancy urine prolan.

When the above methods of treatment have been tried and have failed the use of dilation in the office with small dilators is advised. It has been noted that after a uterus has been measured with Meaker's hysterometer in a patient with dysmenorrhea that the next period may be less painful, and recently it has been suggested that small-sized uterine dilators be passed through the internal os as an office treatment for the same reason. This method of treatment, if done with surgical asepsis, should prove of great value. Dilation, as carried on this way, may be too little and the patient should then be subjected to proper dilation under an anesthetic. This stretching should be thorough and carried out for at least fifteen minutes. At the same time, while the patient is under an anesthetic, it should be noted if there is a tight band about the internal os. This band, similar to the hard band-like tissue found about a pyloric stenosis in infants, can be easily felt on rectal examination. It is not difficult by placing a knife in the cervical canal as far up the internal os and with a finger in the rectum to make an incision directly posterior and cut across the hard band. A small piece of gauze is then placed in the incision to keep the constricting band open and from healing in its original position.

If all treatment has failed so far the patient should have an abdominal operation and a suspension of a flexed or retroverted uterus. At this time a resection of the presacral nerve or superior hypogastric ganglion should be carried out, for this method of treatment has given the highest percentage of complete cures of any procedure except hysterectomy. There are failures even from this operation and the failures are probably due to anomalies of these nerves and lack of section of them. This cannot be avoided and although results are good in nearly all cases they are not absolutely perfect.

The last treatment of all for dysmenorrhea should be

hysterectomy and to advocate this is to fail in the treatment of a condition that in most instances can be helped if not completely relieved.

FUNCTIONAL BLEEDING

Most bleeding of the functional type is due to an ovarian dysfunction and whether the real cause is primary ovarian or primary pituitary is not essential to the understanding of the now known physiology and pathology, and consequently the treatment.

Bleeding accompanied by hyperplasia of the endometrium is the most usual type. In this type of bleeding the uterus or end-organ of the genital tract may be small or large, may contain fibroids or may not. The endometrium in most instances is thick, occasionally polypoid but occasionally very thin. In many instances, microscopically, it shows typical hyperplasia. The hyperplasia is due to either too much estrin or to continuous estrin acting upon it. No progestin influence is present. The ovaries contain a follicular cyst or cysts which are cysts of pathologic physiology and are not neoplastic. These small cysts contain estrin in a greater or lesser amount. There is no evidence of any corpus luteum formation. The pathology of the pituitary in these cases is not known at the present time. The urine of such a patient contains very little or no estrin during the bleeding but after the bleeding has ceased estrin reappears in the urine. The physiology is about as follows: the pituitary being abnormal, produces prolans A continuously; this in turn causes the persistence of a graafian follicle and due perhaps to lack of prolans B, ovulation does not take place. The follicle continues to develop, becomes cystic, and fills with fluid containing estrin. This persistent estrin production causes the endometrium to develop beyond the normal estrin phase and the hyperplasia succeeds the normal proliferative endometrium. As the estrin persists it inhibits the production of prolans A by the pituitary. Then lack of pituitary prolans A in its turn causes a drop in the production of estrin and as estrin diminishes in strength in the cyst sloughing of the endometrium occurs and bleeding takes place. (It is well known that estrin withdrawal is followed by bleeding). The physiology and

pathology of this type of bleeding is known as metropathia hemorrhagica or Shaw, Type I bleeding. The treatment of the condition is obvious. If the cyst could be ruptured the sequence of events would be interrupted; if a luteinizing hormone could be used luteinization of such follicles would follow and the endometrium would change from the proliferative hyperplastic phase to the secretory or corpus luteum phase. Or if a potent corpus luteum hormone could be given in large doses it should change the endometrium to the secretory phase and the later withdrawal of progestin would be followed by menstruation from a secretory phase. (It is now known that if both estrin and progestin are used withdrawal of estrin in the presence of progestin does not allow bleeding but withdrawal of progestin does allow it and it is menstrual [secretory] in type.)

Any method that brought about ovulation in such bleeding cases would be followed by luteinization and thus the normal cycle would be reestablished. It is known that endometrial biopsy and curettage may stimulate ovulation just as copulation with a buck rabbit is necessary for the female rabbit to ovulate. Biopsy and curettage by traumatizing the cervix may be the causal factor in ovulation in these cases and thus be responsible for the return of such cases to a normal rhythm.

The treatment of this condition by means of hormones is not as perfect as it should be theoretically. Estrin by inhibiting the pituitary should stop prolan A from causing estrin secretion and thus should allow normal events to follow, but such does not seem to be the case. The use of anterior pituitary prolan, containing as it does some luteinizing factor, should permit luteinization to take place and thus bring about proper changes in the endometrium. It is said to accomplish this in some instances.

Pregnancy urine prolan, known as the anterior pituitary luteinizing hormone, was considered to bring about luteinization and therefore proper changes in the endometrium, but this is all denied now, as it has been shown that this hormone only causes atresia of the ovary and not luteinization. It does, however, cause theca luteinization and it is possible that this type of luteinization may have some effect on the endo-

metrium. Following the endometrium by means of endometrial biopsy after the use of pregnancy urine prolan is the way to test the efficiency of the method and although in many instances the endometrium does not change, in others a secretory phase has been recognized. It is felt by some that this hormone causes the maturation of a follicle, ovulation, and a corpus luteum formation and thus the absence of many active follicles and corpora lutea in the ovary after treatment is explained. In other words, a single follicle matures as it should and a normal rhythm is brought about. The suggestion of a bleeding factor being responsible is difficult to accept. It is certainly true that in many instances the use of pregnancy urine prolan advocated by the commercial houses and in the doses recommended by them does cause cessation of bleeding and a return to normal. Its use is advised but the exact nature of the physiology is not known.

The use of real anterior pituitary prolan seems more sensible; it may cause the development of follicles and when ovulation follows the cycle returns to normal. Enough clinical experience has not been had to state that this is the best method of treatment but it certainly should be considered and its use is definitely justifiable. Overtreatment might be dangerous because of overstimulation of follicles.

It is conceivable that the use of both pituitary prolan and pregnancy urine prolan in sequence might be of value. The first to cause follicle formation and the second to aid in continuing the follicle on to proper luteinization.

Deliberate rupture of such a persistent follicle would be sound treatment, for interruption of this "middle man" would take pressure off both the pituitary and the end organ, the endometrium. Such treatment would be heroic and although it has been accomplished without disaster to the patient with a cessation of bleeding, it is certainly not advocated.

There are other types of bleeding of functional type and these will be mentioned briefly. At the time of ovulation at the midmenstrual point there is a great congestion of the endometrium and when the estrin level drops, as it does at ovulation, the spilling over of a small amount of blood is often noted. This is a normal process and needs no treatment.

The type of bleeding with a bimonthly rhythm is due to

too frequent ovulation and the exact reason for it is not clear. Too many corpora lutea are found in the ovaries of such patients and though the cycles are too frequent they are nearly normal in character. Inhibition of the pituitary by the use of estrin might help such a condition, and the use of pregnancy urine prolان has been proved of value.

THE MENOPAUSE

The treatment of the menopause is one of the triumphs of female sex hormonology. At the menopause, whether artificial or natural, certain definite findings are present in the urine and blood. There is a fall in estrin to zero and an increase in the anterior pituitary hormone, prolان A. Hot flashes and nervous phenomena follow ovarian exclusion and they may be extremely severe or mild. Large numbers of hot flashes cause sleepless nights and great embarrassment in the presence of friends. To aid such conditions many advocate the use of bromides and luminal and to a certain extent they are successful. The use of estrin, however, either subcutaneously or by mouth, is miraculous and the well-being of the patient as well as a great reduction in the number of flashes occurs almost as soon as treatment is started. The treatment must be kept up, however, for an indefinite period of time, as it is not accumulative. Slowly the patient finds the correct dose that makes her comfortable and her relief is great. When treating the menopause with estrin the appearance of estrin in the urine is not the most important finding in the successful cases. Drop in the level of prolان in the urine is greater evidence of successful treatment.

The dosage should be from 200 I. U. daily to 6000 I. U. daily, by mouth, and from 1000 I. U. to 50,000 I. U. subcutaneously one to three times per week. The dosage must be worked out for the individual patient but with persistence nearly all women suffering from the menopause can be nearly completely relieved.

THE HORMONES

The sex hormone of the anterior pituitary gland (prolan) may be purchased as gyantrin and prephysin. The ovarian hormone estrin is for sale under various names—theelin,

theelol, emmenin, amniotin, progynon, progynon B, folliculin, menformon and sistomensin. The ovarian hormone progestin can be purchased under the name of corlutin and proluton. Pregnancy urine prolan (not to be confused with the anterior pituitary hormone prolan) can be purchased as antophysin, antuitrin S, follutein and A. P. L. With this ammunition we should be able to approach any physiologic upset in the female genital tract. Unfortunately all the commercial hormones

—PROLAN—

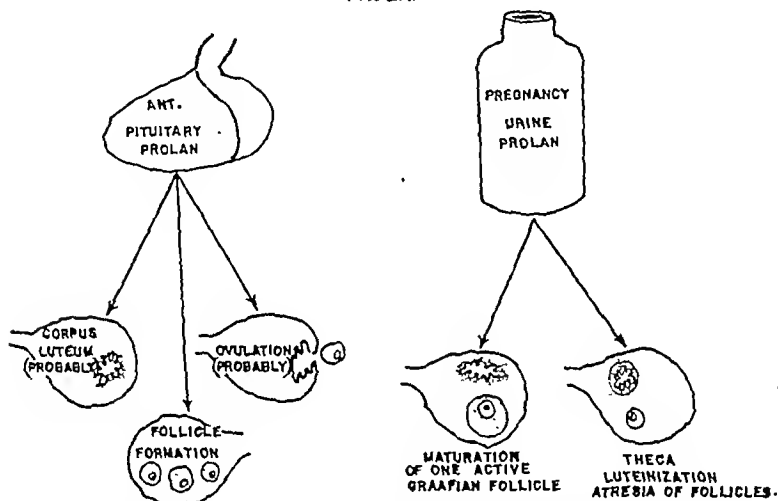

Fig. 170.—The two types of prolan. The anterior pituitary prolan is a stimulator of follicle formation; it causes ovulation and later corpus luteum formation occurs. Pregnancy urine prolan is in dispute. It probably causes the maturation of a fairly well-developed follicle and causes ovulation and luteinization. On the other hand many say that it only causes atresia of follicles and theca luteinization and fails to develop any activity in the ovary at all. These questions must be settled by further investigation.

do not work on humans as they do in the laboratory. There are however certain effects that are of great importance and we can reason our form of treatment from this knowledge. The anterior pituitary sex hormone prolan containing as it does a moderate amount of the luteinizing factor should be able to cause follicle growth and it is reported as doing so in the human. It may only carry the follicle on to full development and not through to ovulation but sometimes this occurs also. If this is true the cases of pituitary failure can be sub-

stituted for and the ovary made to go through its proper cycle, thus cases of pituitary amenorrhea should be helped and successful results have been reported. In cases of menorrhagia where a follicle cyst has been persistent it should be possible to create new follicles one of which might go on to proper ovulation thus relieving certain cases of abnormal bleeding.

Estrin is reported as developing the uterus, as causing hyperplasia of the endometrium, as developing the breast, as changing the vaginal epithelium of children to adult type, and

Fig. 171.—Estrin, and by this is meant any of the chemical forms of estrogenic hormones, has various activities. These are diagrammatically illustrated. It is possible that some of these will be proved untrue but for the present the above diagram gives a working scheme.

as stopping hot flashes. Estrin by its inhibiting effect on the anterior pituitary sex hormone should shut this hormone off and prevent the formation of more estrin in the patient's ovary. If this is possible then by judicious use of it and omitting it at the proper time a shortage of estrin can be brought about before the menstrual period. As estrin causes growth of breast epithelium, as it causes premenstrual feelings or molimina, and as it sensitizes the uterine smooth muscle to the oxytocic principle of the posterior pituitary, if it can be relied upon to check pituitary secretion, it should be

able to relieve painful breasts, lactating breasts, molimina, and dysmenorrhea. The methods of using it are described elsewhere in this paper.

Progestin is an unknown quantity at present but if it acts as a neutralizer to estrin and if estrin causes the irritability of the uterine musculature it should be of value in dysmenorrhea (to prevent cramps), in habitual abortion by preventing irritation of the uterine musculature and should aid proper decidualation and nidation. There is some reason to believe it is of help in these conditions. If metropathia hemorrhagica

Fig. 172.—The action of progestin from the corpus luteum is diagrammatically illustrated. With this hormone available for use in clinics and practice many of the above actions can be proved or disproved.

is due to continuous estrin production with proliferative endometrium perhaps the use of progestin to change the endometrium to the secretory phase might change the whole picture of this endocrine entity. It is considered the hormone that suppresses menstruation and that withdrawal of it is necessary for menstruation to commence.

The so-called "anterior" pituitary luteinizing hormone or pregnancy urine prolan is now an unknown factor. It was considered that it caused luteinization in the follicles of the ovary and hence changed the endometrium from the estrin phase to the secretory phase but both of these virtues are

denied it. It is now looked upon as acting upon the ovary in a dampening way, causing atresia of the follicles and thus not allowing proper development. It apparently does cause theca luteinization but as normal luteinization is supposed to be due to changes in the granulosa cells and not in theca cells it is difficult to understand its value; perhaps theca luteinization may be as important as granulosa luteinization but this is not known as yet. Pregnancy urine prolan does help abnormal uterine bleeding, it checks the bleeding and occasionally changes are found in the endometrium accompanying the cessation of flow. Sometimes one looks for secretory phases in vain, but as the bleeding is checked by it, all sorts of bleeding factors are hypothesized. This hormone has a definite use in uterine bleeding of the functional type.

Thus as far as the therapeutics of female endocrinology is concerned we are not paupers and in the future there is no doubt but that more knowledge will be added and many of the functional disorders will be classified and properly treated.

CLINIC OF DR. ABRAHAM COLMES

BOSTON

RECENT ADVANCES IN THE TREATMENT OF HAY FEVER AND ASTHMA

INTRODUCTION

HAY FEVER and asthma can be considered jointly under one heading, because fundamentally they represent disturbances of a similar nature, one in the nose, the other in the bronchi.

When these two conditions coexist they may be due to the same provocative cause, as noted for instance, in pollen-sensitive patients in whom hay fever and asthma are often provoked by the same pollen, or on the other hand, they may be due to diverse exciting causes. Thus, a patient may have hay fever due to ragweed and asthma due to the ingestion of eggs. Such specificity in the exciting cause of the reaction and such selectivity in the site of reaction, are characteristic of the phenomena of human hypersensitiveness; and it is this hypersensitiveness which in the past has paraded under such diverse nomenclatures as "diathesis," "disposition," "idiosyncrasy," etc., and which has more recently been popularized under its newest adaptation, the term "allergy," that constitutes the fundamental disturbance of which asthma and hay fever are but clinical expressions.

Were we able to correct the fundamental disturbance which permits of the establishment of the hypersensitive state in man and its dependent clinical manifestations, the subject of treatment would be easily dismissed in but few lines. But since this fundamental disturbance is an inherited and integral part of the cellular structure of the body and since all chemical, metabolic and endocrine studies have so far failed to reveal its nature, we must accept it as a fixed and unalterable con-

dition and concentrate on those measures which tend to influence the hypersensitive state clinically. This can be accomplished to a greater or lesser extent in the following ways: by relieving symptoms, by disposing of exciting factors, and by modifying the reactivity of the patient's tissues. Whatever advances have been made in the treatment of hay fever and asthma are directly related to the intelligent application of these measures. This in turn rests upon a clear understanding of the nature and mechanism of hay fever and asthma, and above all upon a correct diagnosis. Hence it is necessary, in the course of our discussion, to dwell upon these phases, even at the risk of digression.

DIAGNOSIS*

If the patient happens to be seen in the attack, the diagnosis of hay fever or asthma is self-evident. The characteristic spasmodic sneezing of the former and the audible spasmodic wheezing of the latter, readily suggest the nature of the ailment. Certain differential possibilities, however, must be borne in mind. Hay fever may be simulated by the common cold, by a foreign body in the nose and by polypoid degeneration of the nasal mucosa, in all of which, sneezing, nasal stuffiness and rhinorrhea may be present. These conditions, however, lack the itchy nose, palate, and eyes, which are so characteristic of vasomotor rhinitis and the strict seasonal incidence of symptoms when pollens are the causative agents.

Asthma must be differentiated from a number of other conditions which are accompanied by continuous or intermittent attacks of dyspnea. The nocturnal dyspnea of the failing heart is characterized by a history of progressive shortness of breath, by evidence of congestion in one or both bases and by the patient's favorable response to digitalis and morphine. The asthmatoïd breathing which often accompanies acute coronary thrombosis comes in the wake of an acute anginal pain, a symptom foreign to the asthmatic state. The stertorous and labored breathing, caused by a foreign body in the bronchi is differentiated from true asthma by its sudden onset and occurrence in a previously well patient, usually a

* The term "hay fever" is used interchangeably with vasomotor rhinitis, for the former is merely a special variety of the latter.

child. The dyspnea that may accompany an enlarged thymus, an aortic aneurism, a pleuritic or pericardial effusion or pressure upon bronchi from mediastinal tumors, is different from the spasmodic breathing of true asthma, with its prolonged expiratory phase, the scattered rhonchi in the chest, the elevated shoulders, fulness in the neck and dependent position which the patient assumes to facilitate respiration. And yet bronchial asthma may coexist with myocardial disease, coronary sclerosis and all other conditions enumerated above. In such instances treatment must be directed toward the amelioration of the coexisting conditions as well, lest our attempt to treat the asthma may fail.

When seen between the attacks, in a symptom-free period, the situation is somewhat different. Here the history of the case is vital. The following points, when elicited, will enhance the possibility of a correct diagnosis:

1. The spasmodic nature of the attack with freedom of symptoms in the interim, especially so in the early cases. In the chronic type, symptoms in a milder form may persist throughout.

2. A tendency to periodicity, the attacks occurring sometimes either spring or fall, or sometimes on week-ends, or during the catamenia in the female, or only during the early morning hours.

3. An incidence in the patient of other manifestations of allergy, such as, eczema, urticaria, migraine.

4. A family history of allergy.

The physical examination during a symptom-free period is not helpful, but a high eosinophile count will emphasize the probability of an existing hypersensitiveness—the fifth characteristic of the allergic state.¹

While such data, when obtained, are strongly suggestive of the nature of the disease, there is another phase to be considered in the diagnosis, viz.: the "exciting factor."

Reference has already been made to the hereditary nature of the fundamental disturbances which permits of the establishment of sensitization in man. The acquisition, however, of the specific sensitivity is not governed by heredity, but by the mere chance of exposure to a variety of substances which, when inhaled or ingested, tend to sensitize the susceptible in-

dividual. Subsequent exposure to the specific substance may result in asthma or hay fever. Hence the history of the case must also deal with the influence of occupation, location, environment and seasonal variations on the patient's symptoms. Examples of these are to be found in bakers who are sensitive to flour, in grooms who are sensitive to horse dander, in druggists who sneeze or wheeze from the inhalation of lycopodium or acacia, in the hay feverite who suffers only during the pollination season and in the traveling man who loses his symptoms when he sleeps away from home, thus escaping from some environmental dust. In other cases the exciting factor is not so obvious and here an exhaustive survey of the case, which may be completed only during several visits and only with the cooperation of an observing patient, is most important. A few examples will be illustrative:

Case I.—A thirty-five-year-old woman residing some 60 miles out of town came in with a history of seasonal "hay fever" and asthma of several years' duration, lasting from June to the end of September. The history was suggestive of pollen disease, since her symptoms concurred with the pollination period of grasses and ragweed. (N. E. states.) Skin tests with all the indicated pollens proved negative. On further questioning it was discovered that the second floor of her house, which was not occupied during the winter, was used for the accommodation of tourists during the summer months. Her symptoms began the early part of June, as soon as she started cleaning the upper floor, and ceased about the end of September, when the influx of tourists ceased and the upper floor was closed again. On a subsequent visit tests were done with extracts from samples of floor dust and bedding from the upper floor and huge reactions were obtained to most of them. By avoiding the upper floor, this patient remained symptom-free throughout the past summer. In this case without a history, the causative agent would have been missed and treatment, therefore, unsatisfactory.

Case II.—A farmer, aged twenty-eight, came in complaining of perennial asthma with aggravation of symptoms from the middle of August to frost. He knew he was "sensitive to horses" but his asthma persisted even when some distance away from the stable. Skin tests were positive for horse dander and also for ragweed. The latter probably accounted for the aggravation of his symptoms during the fall. On further questioning it was discovered that his asthma was also worse whenever he fed the cows. Skin tests with cow dander were negative but he gave a striking reaction to an extract of cow fodder. He then remarked that whenever he spilled the fodder out of the bag he would choke up badly, but he attributed this aggravation of symptoms to effort. Any other effort, however, failed to aggravate his asthma to the same extent. He has avoided contact with cow fodder and his asthma has improved since. Here again, no progress could have been made without a complete history.

Case III.—A girl of seventeen was brought in because of perennial "hay fever" of one year's duration. Skin tests with the most likely offending proteins

were negative. On further questioning we learned that the patient moved to her present residence some eighteen months ago. In back of her house was a leather-finishing establishment where in the process of shaving or "skiving" a lot of leather dust was created. The landlord who lived on the lower floor of the house, was also the owner of the leather shop, and invariably, upon return home from work, would shake his clothes in the corridor, thus disseminating the leather dust throughout the house. At my request, a sample of the leather dust was brought in and extracted, but when tested on the patient's skin, it failed to produce a reaction. Intranasal tests were then resorted to and when a pledget of cotton soaked in the leather extract was inserted into the patient's nose, her "hay fever" was reproduced within ten minutes. None of the controls gave evidence of any such reaction. Subsequently the patient remembered that on a prolonged visit to her uncle, some 40 miles away, she was symptom-free and that upon return home, her symptoms recurred. Needless to say that the history alone led to a correct diagnosis, which, after all, is the backbone of successful treatment.

When we consider the countless substances to which one is exposed in his daily life at home and occupation, and that each substance under suitable conditions can become a sensitizer, one appreciates the difficulty of "spotting" every possible exciting factor. Fortunately, however, experience has taught us that in the majority of cases the exciting cause of the disease is to be found in the patient's immediate environment and in his usual dietary and within this sphere our efforts should be expanded, always of course, bearing in mind broader and more distant possibilities. While the search for the exciting factor is often determined through the history of the case alone, in many instances it may be facilitated by the application of the protein sensitization tests.

TESTS FOR HYPERSENSITIVENESS

The Direct Method.²—The mechanism of the "protein" sensitization test is based upon the reaction which takes place when the specific substance or allergen meets its corresponding specific antibody or reagin. In the case of hay fever or asthma, a similar reaction takes place in the nasal or bronchial mucosa, where it causes edema, and in the smooth muscles of the bronchi, which are thrown into spasm. The most logical method, therefore, of testing for hypersensitiveness, would consist of bringing the suspected substance, or an extract of it, in direct contact with the sensitized tissue, and the resulting reaction observed. This is exactly what was done in the leather-sensitive case described above. There are several dis-

advantages, however, attached to this direct method of testing:

1. The technic is difficult, especially when it comes to introduce the suspected substance into the bronchial tree.

2. One is never certain of the extent of the patient's tolerance for the specific substance and an overdose instilled into the bronchi may result in a severe reaction, even to the point of endangering life.

3. Not more than one or two tests can be done during a single visit.

And yet the direct method of testing proves useful when no reactions to the suspected substance can be obtained by any other methods. To illustrate further:

Case IV.—Miss S. D. has had a persistent cough accompanied by tightness in the chest, of about one year's duration. The history suggested hypersensitiveness as the basis for her trouble. Skin tests with the routine proteins were negative. Further questioning indicated that orris powder might have been the important offender. This the patient was loath to believe, especially in the absence of a positive skin reaction to orris. I then asked her to lend me her powder compact and submitted myself to the inhalation of a thick powder dust created by shaking the puff. Miss D., impressed by the harmlessness of the procedure, submitted herself to a similar exposure with the result that a most distressing attack of cough and asthma followed within a few minutes. The patient, convinced of the effect of powder on her bronchial tree, has given up its use and was "cured." (How simple the treatment can be at times!)

Such a procedure, though drastic, is often needed to prove the point. What is true of orris powder is also true of most any sensitizing substance which can be instilled or insufflated into the patient's nose or bronchial tree. Fortunately, the direct method of testing is not often indicated.

The Skin Test is usually satisfactory. In most instances the patient's skin is involved in the process of sensitization, so that when the suspected protein, in solution, is applied to the scarified skin, a local reaction occurs with whealing, erythema and itching, thus resulting in the so-called "positive" *scratch test*.

When is a skin test positive? Generally a skin test is positive only in relation to other negative tests. A wheal of from 3 to 5 mm. with a surrounding erythema of 8 to 10 mm. is positive if all other tested sites fail to react at all. On the

other hand, if one or two substances produce a wheal of 10 to 15 mm. with a surrounding erythema of 20 to 40 mm., the smaller reactions are only suggestive. Finally, the skin may be irritable and all tests, including the saline control, may react. In such case they are all negative.

Of late this protein skin test has been widely exploited, without due regard to the fact that a positive skin reaction is not always indicative of the cause of the patient's trouble, while at the same time some other nonreacting protein may be at fault. Recent studies³ have indicated that in asthma 40 per cent of the skin-reacting proteins and in perennial hay fever (or vasomotor rhinitis) only 25 per cent are accountable for the patient's symptoms. In seasonal hay fever, the positive skin reactions are accurate in close to 100 per cent. These observations should discourage one from laying too much stress on the skin test alone, but rather utilize it as an adjunct in determining the specific cause of the patient's symptoms.

When by the simple scratch method we fail to obtain a positive reaction to the suspected substance, we may resort to the more delicate *intradermal method of testing*. This is done by injecting the specific extract* in suitable quantity and concentration between the layers of the patient's skin. When positive, a characteristic local reaction with whealing and erythema occurs. While the intradermal method of testing is more "sensitive" than the scratch method, it is also more irritable to the skin and may be productive of many false reactions. Hence its use should be limited to those cases whose "scratch tests" are negative.

Incidentally, a practical and simple method of skin testing consists of soaking the suspected agent in decinormal sodium hydroxide and applying it, *in toto*, to the patient's scarified skin, preferably on the back.⁴ Positive reactions may thus be obtained to a variety of environmental substances, such as rug dust, stuffings from bedding, furniture, etc., and subsequently their clinical importance determined.

The ophthalmic test,⁵ the passive transfer of Prausnitz and Kustner,⁶ the Leucopenic index of Vaughan⁶ and the homely method of trial and error, are additional tests for hypersensi-

* Protein extracts for intradermal use may be obtained from several biological houses.

tiveness. Elimination diets will be referred to again, but space does not permit the discussion of other tests in detail.

The question often arises as to how many proteins should a patient be tested with?*

 The commercial houses put out over 400 protein extracts, altogether too many for the average case. And yet, when one considers the countless substances to which a patient may become sensitized, 400 are too few. Hence, the question should be put: what proteins should a patient be tested with? The answer to this is in the history of the case. Take an account of the patient's occupation, home environment, dietary and the season when his symptoms occur, and then test him with the indicated proteins. Sixty to 80 food substances more than cover the average dietary. But if the history brings out the patient's fondness for duck eggs and turtle soup, test him also with these two foods. Tests with 10 to 15 household allergens are ample for the average case, but if the patient happens to be a chemist and gets his attacks only when in the laboratory, test him with all the chemicals to which he is exposed. In pollen sensitive cases, skin tests should be done with the prevailing pollens of a given locality, a familiarity with which is essential. Generally, one is to remember that the trees pollinate in the spring of the year (March to June), the grasses during the summer months (June and July) and the weeds during the fall (August and September).

OTHER ETIOLOGIC CONSIDERATIONS

While in the main hay fever and asthma may be looked upon as manifestations of human hypersensitiveness, there are instances where such a background cannot be demonstrated. Here a family history of allergy may be lacking and skin tests may all be negative. The symptoms are generally referable to some reflex irritation or to infection. Reflex asthma may be produced through irritation of the sphenopalatine ganglion (asthmogenic area) in the nose or through a pan sinusitis or through stimulation of the vagus through any of its numerous branches, such as cardiac or intestinal. It is generally accepted, however, that reflex symptoms occur only

* See Appendix I.

in such individuals in whom hay fever or asthma has been previously established through some specific cause.

The rôle of infection in the causation of hay fever and asthma is important though its *modus operandi* is speculative. Some observers uphold the view that infective vasomotor rhinitis and infective asthma⁷ are distinct clinical entities wherein bacteria first act as sensitizers and subsequently upon reinfection, as exciting allergenes. Others maintain that bacterial infections lower the threshold of the patient's tolerance for some extrinsic allergen which only then becomes operative and provokes symptoms. Clinical examples which uphold the latter view are numerous. Thus a cat-sensitive patient may be free of symptoms except in the course of a cold, when asthma would set in. A similar cold, in the absence of the cat, does not provoke any asthma. Here infection acts as a nonspecific or as an intermediary cause, which, nevertheless, must be reckoned with seriously, for it stresses the importance of intermediary factors in the causation of respiratory allergy in general. Anything that upsets the patient's physical or mental equilibrium may act as such an agent. On these grounds it is thought that such diverse causes as indigestion, pregnancy, fatigue, constipation, endocrine and metabolic disturbances and even emotional strain, may provoke characteristic symptoms of hay fever or asthma in the susceptible individual. Once a relationship has been established between fatigue and asthma, constipation and asthma, colds and asthma, etc., the symptoms may recur either through a toxic irritation of the neurocirculatory system or on the basis of conditioned reflexes,⁸ unless the chain of continuity is broken. Aside from the fact that intermediary agents are capable of provoking symptoms, they often become real complications of hay fever and asthma. Especially is this true of infection. Whether bacterial infection acts as a direct specific cause or as an indirect intermediary cause, sooner or later it tends to dominate the picture in the form of chronic sinusitis, bronchitis or bronchiectasis. As a result of chronic infection, definite and irreversible tissue changes take place in the nose or bronchi, so that symptoms may continue even though the primary exciting cause has been eliminated. Most obvious are these changes in the chronic asthmatics, where advanced

emphysema and secondary cardiac complications dominate the picture. This group of patients taxes the ingenuity of all of us and contributes considerably to our failures.

TREATMENT

As pointed out in the introduction to this communication, our aim in the treatment of hay fever and asthma is to modify the hypersensitive state clinically. We shall now consider the various measures by which this can be accomplished.

Relief of Symptoms.—The most important remedy at our disposal is adrenalin. It is a sympathetic stimulator and tends to produce vasoconstriction and to overcome bronchial spasm. Three to 8 minims injected subcutaneously or 1 to 2 minims, intradermally, will relieve asthma of average severity and will influence favorably an attack of hay fever. If no relief follows, the dose may be repeated within twenty to thirty minutes. When no response follows repeated subcutaneous doses of adrenalin, the needle may be inserted into the cubital vein and kept there while 1 minim of adrenalin chloride 1:1000 dilution is injected directly into the circulation at three to five minute intervals, until relief is obtained. This may be followed by $\frac{1}{12}$ grain of morphine sulphate or a corresponding dose of pantopon, to secure mental relaxation and a prolonged effect of adrenalin. While large doses of morphine are contraindicated in asthma because of their depressant effect on the respiratory center, small doses ($\frac{1}{12}$ or $\frac{1}{16}$ grain) are indispensable and where all other measures fail, morphine sulphate, judiciously used, is often the remedy of choice. Not infrequently hypersensitiveness to morphine exists and this is the one serious contraindication to its use. Whereas an attack of hay fever can always be relieved with the aid of adrenalin, ephedrine, morphine and atrophine, asthma occasionally becomes intractable and may persist in spite of all efforts at relief. Such cases, though infrequent in occurrence, are so important and trying that at a recent meeting of the Society for the Study of Asthma and Allied Conditions, the management of intractable asthma^o was freely discussed from the floor. The following measures were suggested as worthy of trial in any individual case:

1. Phenobarbital sodium, 2 grains, subcutaneously.
2. Subcutaneous normal saline (in a case of intractable asthma with persistent vomiting).
3. Colonic administration of ether in oil (patient in collapse).
4. Sedation in addition to adrenalin.
5. Oxygen tent.
6. Sodium amytal, intravenously.
7. Caffeine sodium benzoate, subcutaneously in $7\frac{1}{2}$ grain ampules, every fifteen minutes for 3 to 4 doses, or caffeine citrate, 5 to 7 grain doses by mouth.
8. Apomorphine, $\frac{1}{120}$ grain with 1 to 2 grains of codeine and 8 to 10 minims of adrenalin made up together and one third of this administered every five to ten minutes.
9. Sodium iodide (31 grains) intravenously.
10. Morphine and atropine.
11. Two to 3 ounces of whiskey several times a day if needed.

An additional and relatively new method for the relief of intractable asthma is by the continuous intravenous administration of glucose-adrenalin. This procedure consists of administering 5 per cent glucose with a 1: 200,000 adrenalin solution, intravenously, by the constant drip method. In one such recent case where adrenalin, oxygen, morphine and ether failed to give sufficient relief, this solution was administered continuously for thirty hours with complete cessation of symptoms. The flask containing glucose and adrenalin connects to a sensitive valve which permits of a fine adjustment in the rate of flow of the solution in accord with the patient's needs. In our case, 20 drops per minute proved most efficient. By this method, the patient is provided with fluids, calories and adrenalin at one time. A good deal of discomfort arises to the patient from keeping the arm stretched out and fixed on a board to avoid dislocation of the needle, but the intractable asthmatic will accept this instead of the mortifying dyspnea.

There are instances where the response to adrenalin, though favorable, is evanescent, so that a dose may be needed every hour or two. This is particularly unpleasant during the night because it interferes with sleep. In such cases we found a

mixture consisting of three parts of adrenalin and one part glycerin, altogether 2 cc. when injected subcutaneously (with a $1\frac{1}{4}$ inch 25 gauge needle) will give a less rapid but more prolonged adrenalin effect. (The addition of $\frac{1}{4}$ of 1 per cent nupercain relieves the pain caused by the injection of glycerin-adrenalin). In fact, I have often given 1 or 2 minims of adrenalin intracutaneously for immediate relief and followed this by 2 cc. of glycerin-adrenalin for its prolonged effect. The chief disadvantage of this method lies in the painful local irritation produced by the glycerin fraction.

The inhalation of adrenalin chloride 1:100 concentration for the relief of an asthmatic attack has recently been described by Rowe. The author recommends a specially constructed whole glass nebulizer for this purpose.* A very gratifying feature of this method is that the patients obtain relief without the immediate aid of a physician and without the use of a hypodermic needle and long before the full physiologic effect of adrenalin on the circulation, such as tremor, palpitation and pallor, becomes evident.

Ephedrine.—This drug is quite similar to adrenalin in its physiologic effect, though slower in action. It is effective when given orally in $\frac{3}{8}$ or $\frac{3}{4}$ grain doses. When used alone or in conjunction with potassium iodide it is of greatest benefit in the subacute type of asthma. A dose of ephedrine taken in time will often abort a threatening attack. In hay fever, ephedrine is useful when taken orally or applied locally in the form of a spray or jelly. Ephedrine when taken internally may cause restlessness, tremor, sleeplessness and occasionally painful urination in the male. These effects may be partly overcome by combining ephedrine with some sedative. Ephetonin,¹⁰ a synthetic ephedrine preparation, is said to be less toxic, though fully as efficient. A volatile synthetic ephedrine preparation marketed as Benzedrine Inhalant will often palliate an attack of sneezing, though it is ineffective in asthma.

Hypertension, when it occurs in asthma, is no contraindication to the use of either adrenalin or ephedrine. In fact, with the relaxation of bronchospasm, the blood pressure tends to fall.

* The atomizer may be obtained from the Peralta Hospital, Oakland, Calif.

Of the older remedies which still maintain their traditional importance in the treatment of asthma, are stramonium, chiefly in the form of asthma powder, and the iodides. While the former is used mainly in aborting an acute attack of asthma, the latter are more useful in the subacute or chronic stages. The action of iodide is probably systemic as well as local on the bronchial mucosa. Ten minims of the standard solution of potassium or sodium iodide will ease expectoration and reduce dyspnea in a great majority of cases. Although the iodides are readily absorbed through the intestinal tract, they sometimes exert a more beneficial and more rapid effect when administered intravenously. For this purpose sodium iodide in 2-Gm. doses (20 cc. ampule) is available commercially. One, two or even three ampules may be administered within twenty-four hours in stubborn cases.

When the acute attack is over the patient may become either entirely symptom-free and need no further treatment or the presence of chronic bronchial or sinus difficulty may become evident. In either case an exhaustive physical examination including rhinologic, cytologic, roentgenologic and urinary studies are important. An existing pansinusitis, whether it complicates hay fever or asthma, needs surgical interference. The principle underlying such treatment is the removal of diseased tissue and the establishment of ample drainage. In no way, however, must such treatment be aimed at the relief of the underlying disturbance, although incidentally, the patient's outlook for an "ultimate cure" is better in the presence of healthy nasal chambers. In this regard, Weille's studies¹¹ are interesting. Out of a group of 40 asthmatics operated on for pansinusitis, only 12 per cent have had complete relief of symptoms for variable periods of time.

x-Ray examination of the chest will exclude a coexisting tuberculosis, large tracheobronchial glands, pleural effusions, pulmonary tumors, foreign bodies in the bronchi, all of which may tend to complicate the asthmatic state. Most important of all are bronchiectasis and atelectasis, which constitute the most common and most serious complications of asthma. The former is due to bacterial infection, which thrives well in the poorly aerated peripheral bronchial bed, while the latter is due to the plugging of a bronchus with thick mucous secretions

causing collapse of the corresponding portion of the lung. On reexamining patients with chronic asthma, one often notes an absence of breath sounds over a given lung area, which may "clear" suddenly after a coughing spell or within twenty-four hours. At the same time another portion of the lung may become atelectatic.

For the relief of bronchiectasis complicating asthma, postural drainage is the measure of choice. The patient leans over the bed, his hands reaching the floor, and forces himself to cough for a period of three to five minutes. The procedure should be repeated two or three times a day and continued for months. While "cure" is out of the question, relief of symptoms with diminution in the amount of sputum are common following this procedure. Ammonium chloride, T. I. D. in 3 grain doses, will help to liquify the sputum. Recently¹² postural drainage has been suggested in all asthmatic patients on the basis of relieving the "accompanying bronchial and pulmonary exudate."

For atelectasis, the treatment of choice is removal of the plug of mucus through a bronchoscope. This procedure, though unpleasant for the patient, is not dangerous, and is often extremely helpful. Such treatment, however, should not be used promiscuously. The patients should be carefully selected and at the same time should be subjected to a bronchography with lipiodol for further diagnostic details. In fact, repeated lipiodol instillations without bronchoscopic drainage have been suggested as a therapeutic measure in infected asthma. This is not, however, an accepted method of treatment.

Cytologic and urinary examinations may divulge a co-existing blood dyscrasia or a kidney affection, the correction of which will enhance the possibility for better results in the management of asthma or hay fever.

The status of the "heart in asthma"¹³ is still clouded with uncertainty. Logically, the right chamber should suffer because of the increased resistance to the pulmonary circulation in asthma and its frequent concomitant emphysema. x-Ray and electrocardiographic studies, however, fail to substantiate such an assumption. As to dyspnea on effort, the most important symptom of cardiac embarrassment, this is so obscured

by the pulmonary dyspnea incident to the asthmatic state, that the two cannot be differentiated. And yet, a daily dose of $1\frac{1}{2}$ to 3 grains of digitalis in the older patient with asthma, with feeble and rapid pulse, may be of some benefit. Cardiac irregularities, when they occur, must be treated without regard to the coexisting asthma.

The Treatment of the Exciting Cause.—The next step in the treatment of hay fever and asthma is concerned with an allergic survey of the patient. Reference has already been made to the importance of the history in determining the nature of the exciting factor. In this regard, the patient's environment, occupation and dietary have been particularly stressed as the most common sources of trouble. A critical analysis of the skin test has been briefly presented. When neither the history of the case nor the skin tests prove helpful in determining the nature of the exciting factor, the following measures may be resorted to both for diagnostic and therapeutic purposes:

1. *Change of Environment.*—To this end, hospitalization is the procedure of choice. In the absence of such facilities, a change to a friend's or relative's home for a week or two may be helpful. Sometimes a change to a different bedroom, even in the same house, may bring about gratifying results. Relief thus obtained points to the environment as the source of trouble. Upon reentering his home, however, the patient's symptoms may recur. Hence a systematic course of "allergic cleanliness" should be instituted before allowing the patient to reenter his old habitation.

2. *Allergic Cleanliness.*—Allergic cleanliness differs from general "household cleanliness" in that the latter is directed toward the removal of dust, while the former is aimed at the elimination of its source. Experience has taught us that bedding, overstuffed furniture and rugs are the most common sources of active household allergens. Hence the mattresses and pillows should be either changed or encased in rubberized, dust impermeable cloth, while comforters should be substituted by freshly washed blankets. Recently a liquid rubber (Vultex*)²⁴ has been suggested as an efficient agent for protecting pillow and mattress against dust emanation. A coating

* Vultex Chemical Company, 660 Main Street, Cambridge, Massachusetts.

of Vultex is applied with an ordinary brush and allowed to dry overnight. This seals the bedding and makes it dust proof. Rugs and overstuffed furniture should be removed from the patient's bedroom. Closets are dust collectors, hence they should be whitewashed and only freshly cleansed clothing be kept there. Furnace registers are apt to bring in a good amount of cellar dust, hence they should be covered with muslin, which acts as a partial filter. Perfumes, powders, disinfectants, deodorants, moth-killing sprays, are common offenders and should not be permitted in the patient's room. Whatever is washable, such as curtains, draperies, bedspreads, may be left in the room with impunity.

The living room furniture, next in importance, as a dust producer, cannot be handled with the same ease as the bedding. Efforts should be made to obtain samples of stuffing from the divan, chairs, rugs, etc., and each sample should be soaked in decinormal sodium hydroxide and tested on the patient's skin. In the presence of a positive reaction, the stuffing should be changed or the furniture eliminated. When this is impossible, the patient should remain in his own room for comfort. Sun parlor furniture and overstuffed scatter chairs are all possible sources of trouble and should be handled in like manner.

The kitchen is usually least troublesome of all rooms, except for the presence of dusting powders and baking powders, which may be offensive to the patient. Usually, however, the patient is conscious of the ill effects of such products and tries to avoid them. A mouth and nose mask, consisting of 10 layers of gauze and worn while dusting or washing, will act as an efficient filter.

The bathroom should be kept clear of powder and perfumed soaps. Tooth powders and pastes often contain orris root, a common offender, hence, it is my practice to substitute these with common table salt for a trial period.

These measures, in brief, constitute "allergic cleanliness."

3. *Elimination Diets*.—Rowe's elimination diet¹⁵ may be instituted at the same time with allergic cleanliness. A trial period of seven to ten days is ample to determine the effects of each diet on the patient's symptoms. If no relief is obtained within that period, foods are not likely offenders. An-

other form of trial diet consists of limiting the patient to one type of food, such as milk, for a period of three to five days. If improvement follows, additional foods are given each subsequent day, until the "offender" is determined. Where sensitivity to milk is suspected, beef broth or thin gruel with maple syrup may serve as the initial food. (See appendage II.)

Desensitization.—In a good many cases the exciting allergen is elusive, in others, though found, it cannot be eliminated, as often is the case in pollen-sensitive patients or in the occupational allergies. In such instances we must resort to the *third method of treatment*, viz.: an attempt to change the reactivity of the patient's tissues by desensitization. Desensitization may be *specific*, when the treatment is carried out with an extract of the offending substance, or it may be *nonspecific* when any shock-producing agent, such as milk, pepton or tuberculin is injected into the patient parenterally.

Specific Desensitization.—Any substance which is causative of the patient's symptoms and which produces a positive skin reaction, can be utilized for specific desensitization. The first step in desensitization is to establish the extent of the patient's tolerance for the indicated allergen. In the case of pollens, a concentration of 1: 50 can be purchased from any of the several commercial houses and dilutions of 1: 500, 1: 5000, and 1: 25,000, prepared with saline under sterile conditions. Some biological houses offer the pollens already prepared in the various dilutions. The patient's forearm is then cleansed with alcohol and a drop from each of the pollen dilutions is placed over its anterior surface. Using a fine scalpel or the sharp point of a needle, each site is gently scarified, always starting with the weaker dilution and working up to the most concentrated one. Within twenty to thirty minutes a characteristic reaction with whealing pseudopod formation and surrounding erythema will appear. The more concentrated the extract, the stronger the reaction, so that the weaker dilutions of 1: 5000 or 1: 25,000 may fail to react at all. Treatment is then instituted with that dilution which fails to produce any appreciable reaction. 0.10 cc. of such a dilution is a safe initial dose. If the local reaction from the first dose does not exceed the size of a silver dollar, it is safe

to increase the following dose by 0.10 cc. And so each subsequent dose is estimated by the extent of local reaction from the preceding one. An extensive swelling at the site of injection always calls for a repetition or even a diminution of the previous dose. The change from a weaker to a stronger dilution must be exercised with a great deal of care and caution. While there are no fixed rules for this procedure, the following suggestions may be accepted as a working basis:

If the last dose is 0.4 cc. of 1: 25,000 dilution, the next rose may be 0.1 cc. of 1: 5000 dilution.

If the last dose is 0.9 cc. of 1: 5000 dilution, the next dose may be 0.1 cc. of 1: 500 dilution.

If the last dose is 0.9 cc. of 1: 500 dilution, the next dose may be 0.1 cc. of 1: 50 dilution.

As to the number of doses needed in each case, no one can venture to guess, for each patient is a "case unto himself" and his needs are determined by the severity of his symptoms, by the average concentration of pollens in his district and above all by his inherent response to treatment. The first year of pollen treatment is the trial period and the patient should be informed about this at the outset, so that a poor result may not reflect unfavorably on the physician nor on the method employed in treatment.

The aim in pollen therapy, and for that matter in all therapy by desensitization, is to raise the patient's tolerance for the given allergen, to a maximum. In one case it may take 10 pollen doses, while in another 50 pollen doses, to accomplish the same results; moreover, the final or optimal dose may in one instance be 0.1 cc. of 1: 500 dilution, while in another a whole cubic centimeter of 1:50 concentration. Hence, it is fallacious to undertake such therapy with any performed schedule of "doses."¹⁰ One must "feel his way in the dark" and forge ahead cautiously and wait for the appearance of the pollen season to decide on the efficacy of the treatment. Granted that the patient has been brought up to his maximum level, that attempts to further increase the dosage meet with obstinate resistance in the form of large local reactions or even constitutional reactions, does it mean that the patient will have desired relief the coming season? In a large percentage of cases, yes, but in the others relief may be slight or nil. It

is these poor results in pollen therapy that bother us a lot, and so far no one has ventured a final word as to their cause. It is generally accepted, however, that failure in pollen therapy may be due to insufficient treatment, to the existence of additional sensitivities, to structural intranasal abnormalities, to coexisting nutritional disturbances or to an inherent refractoriness of the tissues to therapy. A search for all such factors, and where possible, their elimination or correction may bring about better therapeutic results in the future. At all times, however, it is well to bear in mind that desensitization in man is a *relative* and not an *absolute* procedure and that a heavy pollen season invariably means a larger number of poor results.

There are four generally accepted methods of desensitization. We shall consider them in order of their importance:

1. *Preseasonal Method*.—Here the treatment is instituted four to six months before the expected date of pollination and doses are given at weekly intervals. With the onset of the season, the last dose may be decreased one third and repeated at seven to ten day intervals to the end of the season. If a patient proves resistant to treatment, smaller but more frequent doses may be given at three to four day intervals. An overdose after the onset of the season may precipitate severe and persistent hay fever.

2. *Perennial Method*.¹⁷—At the completion of a season's treatment, the final dose may be maintained throughout the following nine months at four-week intervals. By this time, a change to fresh pollen extracts will necessitate a diminution in dose and from then on the treatment is again continued with increasing doses to the point of maximum tolerance. Not all patients, however, so treated can maintain a fixed tolerance so that after the third or fourth month the local reactions may become large and consequently the dose has to be reduced. After two or three years of perennial treatment, a fairly stabilized tolerance for a higher concentration of the pollens becomes established and only at this time are the results almost invariably satisfactory. A serious disadvantage of this method is the need of constant visits to the doctor throughout the year, which is often depressing to the patient.

3. *Coscasonal Method*.—This is applicable in those cases

who first come for treatment after the onset of symptoms. Here, the daily administration of small doses of pollen extract with the addition of 0.25 cc. of stock catarrhal vaccine every fourth or fifth day is apt to give the patient some relief. Again it should be remembered that an overdose at this time may precipitate most severe and lasting symptoms.

4. *The Rush Method*.¹⁸—A few days before the expected date of pollination the patient is placed in the hospital under close supervision and is given small though increasing doses of pollen at one or two hour intervals. This procedure is repeated for several days and the patient discharged. Though good therapeutic results are claimed for this method, the rapid cumulative effect of the pollens with a possible resultant constitutional reaction nullify its advantages.

Constitutional reactions are best treated by preventing them. This can be accomplished by carefully estimating the indicated dose and by avoiding the injection of pollen directly into the circulation. When it occurs, the constitutional reaction is combated by placing a tourniquet *above* the site of inoculation and by administering adrenalin in sufficiently large doses to overcome the symptoms. I have found that a tight elastic placed above the point of inoculation will retard the absorption of pollens and lessen the tendency to constitutional reactions. This is particularly indicated in patients who are highly sensitive to pollens.

Whatever has been said in regard to pollen therapy is equally applicable to the use of any other allergenic extract for desensitization in either hay fever or asthma. Since the allergenic potency in some substances is more active than in others, it is important to carry the dilutions high enough even to 1:1,000,000, in order to obtain a safe initial dose for therapy.

Nonspecific Desensitization.—Any substance which, when injected parenterally, produces a general reaction in the body, tends to alter the reactivity of the tissues to specific irritants. While the mechanism here involved may actually stimulate the immune processes in the body it is, nevertheless, nonspecific in that the therapeutic results are related not to the substance injected, but to the reaction it produces. Thus, milk, blood serum, whole blood, pepton, sulphur in oil, tuber-

culin and vaccines are commonly used for the production of such reactions. Although the response to such treatment in hay fever and asthma is variable, the procedure is nevertheless justifiable, when other measures fail to produce results. Of the several shock substances suggested for use, milk in 10 cc. doses, 1 to 5 per cent pepton in 1 cc. doses and whole blood withdrawn from the patient's cubital vein and reinjected into the buttocks in 10 cc. doses, are commonly employed. Intravenous injections of all such substances should be guarded against.

Vaccines are the most valuable nonspecific measures. Rackemann's¹⁹ tenets for vaccine therapy: "no reactions, no results," whether one uses autogenous or stock vaccines, still hold good. In our hands tuberculin has not proved advantageous over other types of vaccine. A good stock catarrhal vaccine will usually serve the purpose. In administering vaccines it is well to start with a small dose of 0.25 cc. and increase it by 0.1 cc. at four to seven-day intervals. One always aims to obtain a local reaction the size of a silver dollar. Occasionally we see a patient who is sensitive to bacterial proteins and whose asthma becomes aggravated within two to twelve hours after the injection of vaccine. In such instances the vaccine should be diluted with saline 1:100 and treatment instituted with 0.1 cc. of this dilution. At all times should the dose be kept below its injurious level. Reports in the literature on the particular advantages of autogenous vaccines are not lacking (Thomas-Asthma),²⁰ but in many trials we have never been able to substantiate such claims and an extensive experience shows results with stock vaccines quite the same as those with autogenous.

Oral Desensitization.—When a sensitivity to the ingestion of certain foods is responsible for hay fever or asthma, desensitization by the subcutaneous method is ineffective. Here oral desensitization may be tried. The technic of oral desensitization is as follows: 1 drop of the offending food (egg white or milk) is diluted in 1 quart of water and a teaspoon of the mixture is taken three times a day, after meals. If no ill effects follow, the same amount of food is diluted in a pint of water and again three teaspoons taken a day. The quantity of diluent is gradually decreased from day to day

until it consists of only one ounce of water. From then on the quantity of food is increased instead of diminishing the amount of diluent. Thus we add 2, 3, 4, 5 drops of the food to the ounce of water until the patient is able to take the whole food with impunity. Theoretically this method works out better than practically, but at the same time it is worthy of trial. Nonspecific oral desensitization as had been advocated by Urbach,^{21, 22} at first with heterogenous and later on with homologous propeptons have not created sufficient enthusiasm in this country to deserve unreserved recommendation.

OTHER METHODS OF TREATMENT

Satisfactory results in the treatment of hay fever and asthma with viosterol in high concentration (10,000 units) have been reported by Rappaport²³ *et al.* Commencing about ten days before the expected date of pollination, 4 to 10 drops of the drug are administered daily. Where tolerance permits, the dose may be increased up to 60 minims a day. When treatment with viosterol was combined with specific desensitization the end-results were more satisfactory. The treatment of asthma with hormones of the adrenal cortex and sodium chloride as recently proposed by Pottenger,²⁴ *et al.*, offers a direct approach to the host on the basis of a hormone deficiency. We shall be hopefully awaiting further developments of this method. Beckman²⁵ reports his results on the treatment of hay fever with large doses of hydrochloric acid and finds them comparable to the results obtained from treatment by desensitization. Our own experiences with this method of treatment are scant. The use of nose and mouth masks is often indicated in the occupational allergies, such as in bakers who are sensitive to flour and who fail to obtain palliation through specific desensitization. Such masks, though cumbersome and conspicuous looking, enable the patient to gain some comfort at his work. Air conditioning²⁶ in pollen disease is helpful, at least as long as the patient remains in the air-filtered room. Upon leaving the room, however, the symptoms recur. Hence, air conditioning should be used only as an adjunct to, but not as a substitute for, specific desensitization.

Nasal ionization for the treatment of vasomotor rhinitis as proposed by Warwick,²⁷ has received considerable attention of late. This method is still new and though apparently productive of immediate relief in about 50 per cent of the cases, its possible injurious effect on the nasal mucosa²⁸ calls for rational conservatism.

SUMMARY

In retrospect, the question may arise as to what constitutes the recent advances in the treatment of hay fever and asthma? Since Noon and Freman's introduction of specific therapy in pollen disease and the subsequent application of this method to other forms of vasomotor rhinitis and of asthma, there has been but little progress on this subject. Emphasis, however, has been noted throughout the literature on the fundamentals of allergy and on its chemical and immunologic phases. Only through such broader concepts of the subject is an approach to rational therapy possible. These tendencies are witnessed in Rackemann's²⁹ recent review on the progress of allergy: out of 372 publications he selected 111 as representative of the best thoughts on the subject. Of these 111 only 4 are given to "treatment," while the others deal with the various phases of allergy at large. And yet, clinical experience tends to crystallize the adaptation of current therapeutic measures and these we have attempted to stress in this communication. One other fact is worthy of comment. The allergic concept of asthma and hay fever has sent into oblivion some of the older measures of which physicians, in the preallergic era, availed themselves. Amongst these, balneotherapy, physiotherapy, hydrotherapy, general tonic measures, were most noteworthy. So thoroughly have all these been forgotten, that their consideration anew might justly be included in the "Recent Advances." But the subject is vast and would in itself form an important communication.

APPENDIX I

A suggestive list of foods and inhalants for use in routine skin-testing of patients. This list should be supplemented by such other proteins as may be indicated from the history of the case.

Foods:

<i>Cereals.</i>	<i>Meats.</i>	<i>Fish.</i>	<i>Shell-fish.</i>	<i>Vegetables.</i>
wheat	beef	haddock	crab	potato
rye	veal	halibut	lobster	tomato
barley	lamb	salmon	oyster	asparagus
corn	chicken	cod	shrimp	beet
oats	pork	mackerel	clam	cabbage
rice		flounder	scallop	onion
				carrot
<i>Fruits.</i>	<i>Miscellaneous.</i>	<i>Nuts.</i>	<i>Egg and milk.</i>	
apple	cinnamon	almond	egg white	kidney bean
pineapple	poppyseed	walnut	egg yolk	lima bean
banana	nutmeg	cocoanut	milk (cow)	lettuce
pear	mustard		lactalbumin	mushroom
peach	ginger			sweet potato
plum	buckwheat			
orange				
grapefruit				
grape				
olive				
cheery				
strawberry				

Dusts:

<i>Epidermals.</i>	<i>Miscellaneous.</i>
cat hair	kapok
dog hair	cottonseed
cattle hair	house dust
horse dander	flaxseed
hog hair	orris root
feathers	pyrethrum
chicken	boxwood
duck	
goose	
goat hair	
sheep wool	

Pollens: These vary with different localities. Hence it is essential to establish a familiarity with the important pollen flora, of a given area before undertaking pollen tests. Mr. Durham of the Abbott Laboratories has always been cooperative in rendering such information.

APPENDIX II

ROWE'S "ELIMINATION DIETS"

	<i>Diet No. 1.</i>	<i>Diet No. 2.</i>	<i>Diet No. 3.</i>
Cereal.....	rice	corn tapioca	rice rye
Bread.....	rice biscuit	corn pone	rye-rye
Meat or Fish.....	lamb	bacon chicken	beef
Vegetables.....	lettuce spinach carrots	squash asparagus peas artichokes	tomatoes beets string beans
Fruits and jams and fruit drinks.....	lemons pears peaches	pineapple apricot prunes sugar	grapefruit pears peaches sugar

Miscellaneous.....	sugar	Mazola oil	Wesson oil
	olive oil	salt	salt

CLINIC OF DR. EDWARD S. EMERY, JR.

PETER BENT BRIGHAM HOSPITAL

RECENT ADVANCES IN DIETOTHERAPY

I WANT to present three cases to illustrate the importance which food has come to play in the study and practice of medicine.

Case I.—The first patient is an American schoolboy of fourteen who entered the hospital because of marked weakness and pain in the legs. The family and past history are negative. He lives in unhygienic surroundings and has been a peculiar eater, largely by choice. He has not been eating any fruit and an almost negligible quantity of vegetables. He began to have trouble with pain in his feet last June. He attributes this to fallen arches. He noticed "hard swelling" in the muscles both below and above the knees. Six weeks ago he developed marked weakness, and for the last four weeks it has been impossible for him to walk across the street. For the last few weeks he has had to go about on crutches. He has had sore gums which bleed on brushing the teeth.

Physical examination shows marked pallor of the skin. He is poorly developed. The gums are red. The alveolar tissue is spongy and hypertrophic and ulcerated at the edges. The molars are loose. There is marked tenderness over the epiphyses of the femur and tibia of both lower extremities.

The urine is negative, the hemoglobin is 95 per cent, the red count is 4,530,000, and the white count is 10,500. The blood smear is normal and the platelet count is 335,000.

His only treatment has been an addition to the hospital diet of 200 cc. of orange juice three times a day, which he has received for four weeks. His symptoms and signs have disappeared entirely on this régime. This patient was suffering from scurvy, one of the diseases known to be the result of a vitamin deficiency.

Eijkman's observation in 1897 that fowls acquired polyneuritis on a diet of polished rice gave a new approach to the study of disease. With Funk's contribution in 1910 that beriberi is the result of a deficiency in what he termed a vitamin, the way was cleared for the great progress that has been made in our studies on nutrition. But as so often happens, following new discoveries, our enthusiasm tends to lead us into therapy which our present knowledge does not justify.

It is, therefore, wise to consider how much we know about dietetic therapy.

We have learned much about the vitamins in recent years. We know that the absence of a vitamin can produce severe diseases which clear up almost miraculously with the introduction of the necessary foodstuff.

The disease known as xerophthalmia responds to the administration of vitamin A, beriberi to vitamin B, scurvy to vitamin C and rickets to vitamin D. Also we have learned much about the nature of these vitamins. Vitamin B has been crystallized and has the chemical form of a hydrochloride of picrolonic acid. C is known to be 1-cevitamic acid and D is a sterol. Hence, these substances are chemical compounds which we believe may act as catalysts; that is, they aid or hasten what otherwise may be an ineffective chemical reaction. Vitamin B seems to influence the oxidation of carbohydrates. Vitamin C has been shown to be a strong reducing agent in the test tube. Vitamin D influences the action of calcium and phosphates in the bones although it is not yet known in what way it does this.

We have also learned much about how the vitamins affect the body and its different systems. Vitamin A influences the epithelial tissues of the body and in its absence the skin tends to become cornified. A reduction of tone and motility of the gastro-intestinal tract and a polyneuritis follows a deficiency in vitamin B. An absence of vitamin C results in a lack of an intercellular cementing substance with a resulting leakage or extravasation of blood into the tissues. Vitamin D aids the absorption of calcium from the intestinal tract and seems to influence the chemistry of calcium and phosphorus within the body.

In addition to these facts, which are now generally accepted, there has been a large amount of information reported from laboratory studies which cannot be dealt with completely at this time and some of which is in dispute. Some workers report that vitamin A specifically stimulates the intestinal mucous membrane and directly or indirectly the formation of blood platelets. An atrophy of the intestinal villi is said to occur in the absence of this vitamin. A lack of vitamin B is said to result in congestion and hemorrhage into the bone

marrow. Also it is said to produce an atrophy of lymphoid tissue with a lymphopenia characteristic of nutritional changes.

Interesting as these findings may be, the clinician must remember that they are still in the phase of investigation. If, for example, a lack of vitamin B produces atrophy of lymphoid tissue and a lymphopenia, it does not follow that the finding of a lymphopenia should necessarily be treated with vitamins.

The question of how far we should go in using vitamins is hard to evaluate at the present time. Some very good men have advanced the idea that many symptoms may be the result of an insufficient amount of these substances. However, we must not forget that a very small amount of a vitamin is required to eradicate completely all vestiges of those conditions like scurvy, which are known to be caused by an inadequate intake of a vitamin. Therefore, one should be cautious about attributing other conditions, frequently with indefinite symptoms, to an insufficiency of vitamins, particularly if the patients seem to be taking a normal diet. Certainly it is true, that in this period when the population is "vitamin conscious" very few persons take an insufficient quantity. The diet of most adult Americans contains enough vitamins to prevent the picture of a severe insufficiency such as occurs in beriberi and scurvy. The present free use of vitamin mixtures either with or without a doctor's sanction would seem to preclude an insufficient intake in most patients.

Therefore, if indefinite complaints of bodily aches, chronic indigestion, lack of vitality, etc., depend upon a vitamin lack, it is reasonable to believe that in some cases the difficulty may be an inability of the body to utilize the vitamin rather than an inadequate supply.

The second patient illustrates another group of diseases which can be relieved by diet.

Case II.—This thirty-six-year-old married clerk entered the hospital because of persistent weakness and fatigue of two years' duration. The family and past history are irrelevant. She felt perfectly well until twenty-two months before admission when she caught cold and suffered from headache, malaise, anorexia, weakness and fever. She remained in bed for four and a half months after which she began a slow convalescence which was marked by fatigue, dyspnea, palpitation and weakness. By fall she was able to work half a day but with great effort. Two months ago she was attacked suddenly by what she described as an "awful dead, all gone feeling." Her physician said

It is, therefore, wise to consider how much we know about dietetic therapy.

We have learned much about the vitamins in recent years. We know that the absence of a vitamin can produce severe diseases which clear up almost miraculously with the introduction of the necessary foodstuff.

The disease known as xerophthalmia responds to the administration of vitamin A, beriberi to vitamin B, scurvy to vitamin C and rickets to vitamin D. The second patient illustrates another group of diseases which can be relieved by diet.

Case II.—This thirty-six-year-old married clerk entered the hospital because of persistent weakness and fatigue of two years' duration. The family and past history are irrelevant. She felt perfectly well until twenty-two months before admission when she caught cold and suffered from headache, malaise, anorexia, weakness and fever. She remained in bed for four and a half months after which she began a slow convalescence which was marked by fatigue, dyspnea, palpitation and weakness. By fall she was able to work half a day but with great effort. Two months ago she was attacked suddenly by what she described as an "awful dead, all gone feeling." Her physician said

she was anemic and advised rest. About three months before entry she began to be troubled with nausea, vomiting and gagging after eating.

Physical examination revealed an emaciated woman with a lemon yellow tint to the skin. The face was drawn. The sclerae were very white. Many flame-shaped hemorrhages were present in both fundi. At the time of entry her hemoglobin was only 15 per cent, red blood count 880,000 and white blood count 3800. The red cells showed marked achromia, anisocytosis, poikilocytosis, normoblasts, polychromatophilia and stippling. No platelets were seen. Following one transfusion and intramuscular injections of liver extract she began to improve. After one month the hemoglobin was 86 per cent, the red blood count was 5,480,000 and the white blood count was 8500. Now she feels perfectly well.

This patient suffers from pernicious anemia, a disease which presents, or at any rate emphasizes, certain problems which scurvy does not. Scurvy develops in a normal person from an inadequate supply of vitamin C, whereas pernicious anemia may occur on a normal diet with an inadequate gastric function. The patient with pernicious anemia develops symptoms because of an inability to manufacture from a normal diet something essential to the body. Therefore, the clinician must remember that there are at least two factors in the study and treatment of deficiency diseases. One is the amount of essential substances available in the diet. The other is the ability of the body to utilize these substances.

With our present limited knowledge of the subject, it is alluring but dangerous to speculate on how many of our medical problems are associated with a deficient state. Pellagra and sprue are two clinical entities which seem closely allied to pernicious anemia. Both are benefited by dietetic treatment. Brewer's yeast and fresh liver are said to be especially rich in the pellagra-preventive substances. Sprue is reported to be relieved by liver extract. Although the three diseases have certain qualities in common they present a sufficiently characteristic picture to make possible a clinical differentiation. We have yet to learn what causes these various pictures. Are they the result of a difference in the utilization of the same foodstuffs, and if so, upon what does the difference in utilization depend? As an evidence of how little we know about this problem is the fact that as late as 1934 one of the standard textbooks retained sprue under the infectious diseases. Our lack of knowledge about this group of diseases emphasizes that we should not expect to cure all patients that

suggest a deficiency by the simple means of giving a normal diet.

Finally, I want to present very briefly this last case for your consideration because it involves the mineral content of the food.

Case III.—This young boy of ten years was brought into the outdoor department following an automobile accident. He was not hurt seriously, but an x-ray was taken of his leg for a possible fracture. The film revealed a healed rickets. The patient is now well but is of interest because he shows evidence of a former illness which was produced by a diet inadequate in vitamin D, phosphorus, or both. The case is an example of the importance which diet plays in providing the body with sufficient minerals.

Our knowledge about the effect of minerals on the body has increased rapidly of late. We have learned that certain minerals are essential to the normal functioning of tissues, as for example, iodine in relation to the thyroid, iron to the blood, calcium and phosphorus for the bones.

The salts maintain the reaction of the blood and control the osmotic pressure in the organism. An imbalance in the amount of the various minerals and salts results in widespread systemic effects. Alkalosis is met with not uncommonly from continued loss of chlorides through vomiting and the alkaline treatment of peptic ulcer. Many of the symptoms of heat exhaustion have been traced to an excessive loss of sodium chloride in the sweat.

Our recent knowledge has supplied us with therapeutic triumphs. The treatment of heat exhaustion with sodium chloride is of distinct value. The great contribution to our therapy in lead poisoning came from Aub's study of the behavior of minerals within the body.

More recently it has been reported that an acid base diet is useful in treating patients with renal calculi of a certain type.

We can look forward to further advances in therapy. Further knowledge of the chemical behavior of minerals within the body should open the way for a more efficient treatment of edema. But such advances can only come through the information obtained from careful laboratory studies. Meanwhile the profession must guard against foolish therapy based on inadequate knowledge. It is worth emphasizing that the

amount of minerals which the body requires is small. The normal adult needs roughly 0.015 Gm. of iron, 1.32 Gm. of phosphorus and 0.68 Gm. of calcium per day. Therefore, the actual needs of the body are easily supplied. The profession is facing the same problem that has so often presented itself with any new knowledge. The public will become "mineral conscious," and we can look forward to a wave of injudicious treatment.

Only the discriminating use of our new knowledge by the profession can serve as a brake against foolish therapy and quackeries which always arise at such a time.

CONTRIBUTION BY DR. FREDERICK T. LORD

BOSTON

CERTAIN ASPECTS OF THE COMMON COLD

LITTLE is known regarding environmental factors as a cause of colds. The hypothesis is presented by Kerr and Lagen¹ that the disease represents a failure of the body to adjust itself to a varying environment, as against an infectious origin. In support of this theory, presumably susceptible subjects under conditions arranged for maximum comfort, failed to develop colds under intimate exposure to individuals in the early stages of the disease or after inoculation with nasal secretion from persons with colds.

The greatly increased incidence of colds during the colder months of the year lends support to atmospheric conditions as a factor. Van Loghem² noted that epidemics of colds in Holland follow sharp drops in temperature. Milam and Smillie³ also found that outbreaks of colds in the tropics coincided with sudden fall in temperature of a few degrees. Paul⁴ states that epidemics of colds occurred on the research vessel Carnegie after many days or weeks out of port after the ship entered a cold current from warmer waters.

The investigations of Rossbach,⁵ Müller,⁶ Miller and Noble⁷ and Mudd, Grant and Goldman⁸ suggest that chilling of the body surface in animals and man may induce changes favorable to local invasion of the mucous membranes by organisms already present and otherwise harmless.

⁷ Jour. Exp. Med., 24: 223, 1916.

⁸ Ann. Otol., Rhinol. and Laryngol., March, 1921.

In spite of such observations, there is nothing to support the belief that environmental factors alone are of importance. The great frequency of exposure in wet weather, wet feet, sitting in wet clothes or draughts and rapid cooling when overheated without ill effects is suggestive of little more than a chance relation. It is difficult to estimate the importance of lowered temperature, in view of the tendency in cold weather to live in crowded and poorly ventilated rooms with consequent greater opportunity for spread by contact.

Nansen's often quoted experience of freedom from colds among members of his expedition under exposure to the rigorous climate of the far North is against exposure to cold as a factor. The development of colds and coughs among many of his party when, on their return, they landed at a thickly settled port, is strikingly suggestive of a contagious origin.

The investigation of small isolated communities has apparently established spread of the disease by transmission from person to person. Studies in certain Eskimo settlements (Greenland) by Heinbecker and Irvine-Jones⁹ and in Longyear City (Spitzbergen) by Paul and Freese¹⁰ indicate that outbreaks of colds arise from exposure to persons from without and involve a large proportion of the population. Paul and Freese find in a group of 500 persons in Longyear City that colds are largely concentrated into an explosive epidemic following the annual resumption of steamer traffic with Norway. They suggest that the population is too small to permit transfer of the inciting agent from person to person with sufficient frequency to retain its original virulence and give rise to an epidemic during the months of isolation from the outside world.

A filtrable virus was suggested as the cause of colds by the investigations of Kruse¹¹ and Foster.¹² Dochez and his associates have made additional contributions of great value. They find that anthropoid apes and especially chimpanzees are susceptible and that infection is readily communicated from man to the ape and from one ape to another. The dis-

¹² Jour. Amer. Med. Assoc., 66: 1180, April 15, 1916.

ease can be produced in an experimental subject by inoculation with filtered nasal secretion from an individual with a cold, the organism recovered by culture and the disease reproduced by inoculation with the culture material. The inciting agent remains active after many generations of growth in tissue cultures. Production of colds with bacteria-free filtrates excludes the presence of ordinary organisms as a cause. The constituents of the culture material itself and the heated culture of the virus at times produced temporary irritation, but not the manifestations of colds. An origin of colds from infection with a filtrable virus must be regarded as established.

As with other infectious diseases, not all persons appear to be susceptible. Following a cold there is a short period of immunity, the duration of which may be estimated from the observations of Paul and Freese at a minimum of twenty-three days and an average of seven weeks. Dochez's experiments on chimpanzees indicate that resistance to reinfection lasts only about a month. A short period of immunity increases the difficulty of solving the problem of prevention by any method of artificial vaccination.

Investigation of the flora of the nasopharynx under normal conditions and during colds by Dochez and his associates, Burky and Smillie,¹³ Kneeland,¹⁴ Milam and Smillie¹⁵ and Paul and Freese¹⁶ suggests that the bacteria harbored in the upper air passages are not to be regarded as the inciting agents of the disease. They play an important part, however, as secondary invaders. The seriousness of a cold is almost entirely due to its tendency to initiate such disturbances of a grave nature as bronchitis, otitis media, sinusitis, bronchopneumonia and lobar pneumonia. Among patients with lobar pneumonia, for example, 76 per cent give a history of a cold within a short period of the onset of pneumonia. Smilie and Caldwell¹⁷ found pneumococci increased in the nasopharynx or persons with acute colds, and Dochez, Mills and Kneeland¹⁸

¹⁸ Proc. Soc. Exp. Biol. and Med., 30: 314, Dec., 1932.

noted in chimpanzees during the early stages of the cold, whether spontaneous or experimental, a great increase in the numbers and the area of distribution of the common pathogens of the upper air passages, such as the influenza bacillus, pneumococcus and hemolytic streptococcus. Under the influence of infection of the animals with the virus of the common cold, a transformation was observed from the S to the R type of influenza bacillus during the period of the cold, while only R forms could be cultivated during the intervening period. Such observations suggest that one of the most important effects of the virus of the cold is to incite activity on the part of potentially pathogenic micro-organisms present in the nasopharynx at the time of infection.

There is no practical method for the prevention of colds under ordinary conditions of life and none of the numerous measures suggested has been proved to be successful. The difficulty of avoiding contagion is suggested by the observation of Heinbecker and Irvine-Jones¹⁹ that it was not necessary for members of the expedition to have a respiratory infection for the disease to appear among the natives. It is, nevertheless, desirable to attempt to prevent colds in infants, invalids and the aged by the avoidance of known contact and in them special care should be exercised against exposure to rapid changes of temperature. Adequate ventilation, maintenance of an equable temperature within doors and humidification may prevent the development of complications in those who have colds.

On the part of those with colds, for the protection of others, precautions should be taken to prevent droplet and contact infection. It is possible that transfer of bacteria heightened in virulence by the inciting agent of the cold may more readily give rise to infection on transfer to others.

There is no evidence that hardening or toning-up processes, ultraviolet radiation, vitamins or nasal douches are useful in prevention. Vaccination with a mixed vaccine containing killed bacteria ordinarily found in the nasopharynx has not, on the whole, proved successful in diminishing the incidence of colds when large controlled series have been investigated.

Inoculation with a composite vaccine has been proposed

¹⁹ *Loc. cit.*

for the purpose of diminishing the frequency and severity of the complications of colds. Kneeland²⁰ compares the results in 23 infants given a course of 9 and later of 7 inoculations, with an equal number of controls. There was no difference in the incidence of minor respiratory infections of the type of the common cold in the two groups. The severity of the subsequent respiratory disease measured by the duration of fever, however, was diminished and there were 2 cases of pneumonia in the vaccinated against 5 in the controls. Further carefully controlled experiments of a similar nature are desirable before a favorable effect can be regarded as established.

Colds are self-limited. There is no specific treatment. Symptoms may be relieved and it is possible that complications may be averted by observance of certain precautions. In all cases, while there is fever, rest in bed is desirable. Irrespective of fever, in the more severe types and in infants and the aged or infirm, rest in bed is also advisable. During the disease and also while cough and expectoration persist, caution should be exercised against fatigue, chilling of the body, exposure to draughts without sufficient clothing and rapid cooling when overheated. An abundant intake of fluid is to be recommended and a mild laxative, if necessary, for constipation.

Headache and general discomfort may be alleviated by acetyl-salicylic acid (aspirin), 5 grains, repeated if necessary, every four to six hours for 4 to 6 doses, or such coal-tar products as phenacetine, 3 grains, with caffeine, 1 grain, repeated if necessary, every three hours for 3 or 4 doses may be used if these symptoms are sufficiently troublesome. It is undesirable to use amidopyrine or drugs in combination with it, in view of its probable implication as a cause of agranulocytosis in susceptible individuals. If the headache and general pains are especially distressing, Dover's powder, 10 grains, may be ordered. In the investigations of Diehl²¹ the highest percentage of good results followed the use of a combination of codeine and papaverine; *i. e.*, "co-pavin," containing codeine sulphate $\frac{1}{4}$ grain and papaverine hydrochloride $\frac{1}{4}$

²⁰ Jour. Exp. Med., 60: 655, 1934.

²¹ New York State Jour. Med., 35: 109, Feb. 1, 1935.

grain. Toxic symptoms occurred in 4.9 per cent of the cases. In his experience, this preparation as well as certain other opium derivatives were followed by prompt diminution of complete relief of nasal discharge and congestion. The routine use of opium or its derivatives does not seem justifiable, but may be desirable in unusually severe cases. The local application of 1 per cent ephedrine sulphate dropped in the nose produced temporary relief of nasal congestion, but the progress of the cold was apparently unaffected. Toxic symptoms were observed in 4.3 per cent.

CLINIC OF DR. WILLIAM H. ROBEY

BOSTON CITY HOSPITAL

THE SIGNIFICANCE AND INTERPRETATION OF HEART MURMURS IN GENERAL PRACTICE

If you are surprised that one takes the time to discuss this subject when so much study is being given to the problems of cardiac muscle efficiency, let me remind you that the cardiac murmur is still a puzzle to many general practitioners. In my student days no cardiac sign was given as much thought as the murmur, and its discovery often meant a diagnosis of organic heart disease, even when the patient was apparently in perfect health, since it was impossible for the doctor to believe that a heart could emit such a sound unless diseased. As a result, a diagnosis of cardiac disease was made and the patient's life restricted; with the further result, in some cases, of transforming a healthy person into a hypochondriac. For several years I gave a course to graduate students, principally those who had been undergraduates during the days when the cardiac murmur was considered to be of such great importance. Upon being asked to examine a heart, the student immediately placed a stethoscope over the valve areas and his opinion was formed by the presence or absence of a murmur. Before the end of the course the students were trained to evaluate the medical history and many cardiac and circulatory signs before using the stethoscope. Undergraduates were also taught to diagnose well-marked cases of mitral stenosis by palpation of the precordium and the radial pulse before listening to the heart. The idea was to instill in the mind of the student the necessity of merely adding a murmur to the other physical signs rather than allowing the murmur to become the dominant factor in cardiac diagnoses. The physician must constantly remember

that serious heart disease, such as syphilitic aortitis, hypertensive heart disease and coronary disease, may exist without any murmurs. I once saw a forty-seven-year-old man, apparently in the pink of condition, who had no cardiac nor circulatory defect which could be discovered, but who had repeated attacks of most severe nocturnal angina pectoris, one of which terminated in sudden death. Again, some conditions, while slight, may give rise to loud murmurs which disappear with a serious advance of the disease. In hypertensive heart disease a sudden drop in pressure and the disappearance of a mitral systolic murmur are often ominous signs of cardiac muscle failure. In mitral stenosis the presystolic diastolic murmur generally disappears with the onset of auricular fibrillation, although not always.

The mechanical causes of murmurs, such as changes in viscosity of the blood or stretching of the valve rings, have been discussed for years and need not concern us now. The important points to remember are the following:

Murmurs are caused by the vibration of the valve cusps and walls of the heart and of the great vessels when the blood flows from a passage of narrowed caliber to one of much greater caliber, or by the vibration of some tissue attached to a valve, to the heart wall, or to a vessel wall, with the other end free to move in the blood stream. Speed and strength of the blood flow are the factors which intensify or diminish the sound of murmurs. If the flow is strong the murmur will be loud, if of decreased strength the murmur will be faint, while it may disappear completely if the flow loses power to a marked degree. In mitral stenosis, for example, when the left auricle is well compensated and the valve is somewhat distorted, a rough, vibratory presystolic type of diastolic murmur is heard, but when the auricle goes into fibrillation the speed is increased but the strength of flow is reduced so that the murmur subsides or varies in degree of intensity, or it even may cease to exist.

Another cause of murmurs is edema of the cardiac structures which occurs in some of the acute infections, especially rheumatic fever. Such murmurs must be classed during the illness as functional and not as organic until their character and permanence can be determined. Therefore, when mur-

murs are heard during an acute illness, the attending physician should not give a hasty opinion as to their significance.

Murmurs, like other heart sounds, may be louder in thin persons and fainter in the obese or muscular. Emphysema may diminish the intensity by pushing the heart away from the chest wall. Fluid accumulating within the pericardial sac, especially when evenly or anteriorly placed, will render less clear all heart sounds.

THE SYSTOLIC MURMUR

As has already been said, the systolic murmur has been the cause of much perplexity in the minds of examiners. During the World War it was, of necessity, given considerable attention; doubtless many healthy young men were declined for service merely because of a sound which suggested a systolic murmur. Some, however, were enlisted and the regimental surgeon sent them to the base hospital with the question of discharge. The consultant's duty was to decide whether the murmur was organic or functional—whether or not it was indicative of some organic lesion which would declare itself under the stress of action. We went into the medical history with great care and looked for further signs. If the findings were otherwise negative we made a diagnosis of functional murmur and signed the soldier for full duty. Similarly Sir Thomas Lewis returned thousands to the front who proved able to carry on successfully. Some have even gone to the point of saying that the mitral systolic murmur is of no importance, and that it may be disregarded in the young unless there are indications of mitral stenosis. Indeed, this might be so, were it not for the fact that the first murmur of mitral stenosis is sometimes the mitral systolic murmur. And the opinion that valvular findings are unimportant would also be true, since the myocardial condition is the one which determines the efficiency of the circulation, were it not that the state of the valves, especially in the young, regulates in a measure, the amount of work which may safely be thrown upon various parts of the heart muscle.

When I read some descriptions of the differentiation between functional and organic systolic murmurs, I am reminded

of one of our professors whom I, as a student, asked when a case of appendicitis should be operated upon. He replied, "Show me the case." Laënnec in 1819 described sounds in the heart which he considered were always caused by valvular lesions, but later he denied them any value because the post-mortem examination often failed to show the lesion which had been foretold by the murmur. This failure to discriminate between functional and organic murmurs continued for years, notwithstanding our great advance in the interpretation of cardiac and circulatory signs; even today some confusion on this point continues to exist.

The two chief findings in the determination of a systolic murmur are duration and intensity, and of these, the former is the more important. To make a definite diagnosis of a systolic murmur the bruit must have an appreciable duration after the first sound, and continue into systole. Do not mistake a slight prolongation of the first sound for a murmur.

Short, faint systolic murmurs are considered functional and of little importance, while prolonged intense ones are thought to be organic. Levine¹ grades mitral systolic murmurs by their intensity, which he divides into six degrees, beginning with the first, which is very faint and which he says few general practitioners hear, and ending with the sixth, which is rare, but so intense that it can sometimes be heard when merely standing in front of the patient (in my own experience I remember but one such extreme case) and physicians working with him in the clinic were able in most instances to estimate the degree of intensity of a murmur and were usually in entire agreement. This is a very interesting method for a group under expert leadership, but for those who must work alone and whose training may not have been specialized, it offers comparatively little that is of practical advantage.

Intensity is important, but differing conditions in patients suffering from the same lesion may cause it to vary—this refers to emphysema, thick chest wall, and the degree of cardiac muscle strength. Duration can be more easily determined following the rules already given.

While systolic murmurs are said to occur rarely in normal individuals, many are heard without other evidence of cardiac

¹ Jour. Amer. Med. Assoc., 101: 436-438, Aug. 5, 1933.

disease. When one is heard we immediately attempt to decide whether it represents organic valvular disease or is merely a functional murmur. Regurgitation of blood through the mitral valve produces a systolic murmur over the area of cardiac impulse, but regurgitation of blood and its systolic murmur do not necessarily indicate disease of the mitral valve. When the New England Heart Association in 1926 made a survey of the 119,337 school children of Boston, 2311 who, because of murmurs, were suspected by the school physicians of some type of heart disease, were examined and separated into groups. The majority, 1344, could be safely reassured they had no significant disease. The doubtful group, 265, required reexamination until the diagnosis could be settled. The potential heart disease group needed to have the importance of their condition brought home to them. The most important discovery was the small number of children having organic disease—only 160 were in hospitals, and these, added to the ambulatory cases, totaled 785, or the surprisingly low percentage of 0.66 of discovered cases. In one room where there were 52 young children, every one had what the school physicians called a systolic murmur, and yet the medical history, physical well-being, activity and absence of other cardiac abnormalities made us pass the hearts as normal.

Conditions which dilate the left ventricle may enlarge the valve opening so that perfectly normal valve cusps may not be able to approximate and will therefore fail to prevent a reflux of blood from ventricle to auricle during the contraction of the former chamber. On the other hand, the chambers of the heart and the mitral ring may be normal, yet the cusps are retracted, the valve is incompetent and a murmur occurs during ventricular systole.

A mitral systolic murmur in a young person, especially if it has the proper duration and some degree of intensity, should be looked upon as evidence of organic valvular disease until we can satisfy ourselves that it is functional, while a similar murmur in an elderly person is very apt to be functional and not caused by any pathological changes in the valve itself, but is a result of cardiac muscle pathology. In fact, many serious cardiac disturbances in the elderly occur without any murmur. In the young it is far more important,

meaning, as it does, when we have proved it to be organic, a pathological condition of the valve which gradually throws more work upon adjacent chambers and eventually causes an inefficient heart.

How are we to determine whether a mitral systolic murmur is functional or organic? First of all, there is the medical history. Has the patient ever had rheumatic fever or its allies? We must remember that rheumatic fever in a child frequently has quite a different train of symptoms from that in an adult; he may have a sore throat, vague pains in the muscles, fever, nervousness and irritability; or there may be repeated attacks of sore throat without other symptoms which the patient or his family are able to recall, but the hot, red, painful joints of the adult are often not in evidence. The diagnosis of rheumatic heart disease is almost certain, even if the other signs of mitral stenosis cannot be demonstrated, provided one finds that the murmur has duration and a certain degree of intensity combined with a history of rheumatic fever.

A seventeen-year-old girl was brought to my office with a history of always being delicate. During the summer she had lost 12 pounds, although she was on a farm. She gave a history of rather frequent colds but no rheumatic fever, sore throats nor tonsillitis. Occasionally there was nose-bleed. She had a good appetite and slept well; her chief complaint was very easy fatigue. If she went out for an evening she would be tired the following day. She was thin and of poor color. The blood pressure was 130-90. The heart was normal to percussion and fluoroscope with a loud, blowing systolic murmur heard over the entire precordia and in the back. The impulse was heaving and the cardiac rate 120. There was no arrhythmia, no diastolic nor presystolic murmur, no thyroid enlargement, no cardiac thrill, no tremor of hands, no incoordination. The lungs and abdomen were negative. There was no edema. The hands were cold and slightly cyanotic. In the differential diagnosis, I considered first mitral stenosis and then effort syndrome and hyperthyroidism. In view of the fatigue, occasional nosebleeds and marked systolic murmur, the mitral stenosis seemed most probable. She was given a régime of rest and quiet with instructions to report in two weeks, but six days after I saw her, her mother stated that her daughter had a paralysis of the left arm and leg. This clarified the diagnosis of mitral stenosis. Two months later I saw her in consultation with her physician and found, in addition to the hemiplegia, a systolic murmur, diastolic and presystolic murmurs and a marked apical thrill. The pulse was small and 140 in rate.

Another girl entered the hospital many years ago with a systolic apical murmur of moderate intensity without any murmurs during diastole. There was no history of rheumatic fever but there had been occasional attacks of nosebleed. She was discharged with a diagnosis of mitral regurgitation but

returned in about two weeks with a diastolic murmur in addition to her systolic one and a certain amount of arrhythmia. This made the diagnosis of mitral stenosis quite apparent.

If we can satisfy ourselves that there is some cardiac enlargement with a persistent mitral systolic murmur it can be assumed that there is organic valvular disease. Similar findings in a middle-aged person who is developing easy fatigue, breathlessness on exertion or during sleep, or some type of arrhythmia doubtless would indicate organic cardiac disease but the murmur is merely relative. During the course of rheumatic fever, the physician should reserve his opinion about any murmurs he may hear until the fever has entirely subsided and the patient's convalescence has been well established.

A fourteen-year-old girl was on our service at the Boston City Hospital with a violent and prolonged attack of rheumatic fever, and during the height of the disease she developed a well-marked presystolic murmur. There was a temptation to make a diagnosis of mitral stenosis but it seemed incredible that such a condition could have developed in so short a time, and the diagnosis was held in abeyance. As convalescence progressed nothing was heard in the heart but a soft, blowing systolic murmur. Doubtless this girl eventually had the signs of organic mitral stenosis, but at the time we heard the presystolic murmur she probably had a functional stenosis due to edema about the valve ring and when the inflammation subsided the edema disappeared, and with it the murmur.

Winternitz and his associates have demonstrated the reason for the appearance and disappearance of these murmurs, but Sir James Mackenzie in reporting two such cases gives no explanation.

Basal systolic murmurs are principally heard at the so-called aortic and pulmonic areas. Not infrequently a soft, blowing systolic murmur is heard over the aortic area in the middle-aged and elderly, particularly among males, and is an indication of sclerotic changes in the aortic ring. The murmur is often transmitted to the pulmonic area and with diminishing intensity to the mitral region. It may have for a long time no accompanying signs, but more frequently there is some widening of the great vessels, a sharp closing of the aortic valve, an increase in the measurements of the heart, and some heightening of the blood pressure, particularly the diastolic. I have known physicians to interpret the aortic systolic mur-

mur as a sign of aortic stenosis but the murmur of that lesion is quite different. The latter is definitely limited in area, often no larger than the bell of a Bowles stethoscope, is rough and grating in quality, as stenotic murmurs are apt to be, is accompanied by a palpable thrill, absence of the second sound, and transmission to the vessels of the neck. The murmur of early stenosis may be very slight but with increasing obstruction to the blood stream it may become extremely loud, and when transmitted to the entire chest it may on occasion be heard a short distance from the wall with the unaided ear; in addition, there is the plateau or sustained pulse. With stenosis there is also regurgitation in most cases, and therefore a diastolic murmur.

The systolic murmur at the pulmonic area is frequently heard and is the commonest of all murmurs. It may be audible when the patient is lying down and not at all in the upright position. Unless it is heard with considerable intensity in both positions it may be classed as functional or physiological. The murmur is often of a soft, blowing quality, which begins early in systole and extends through most of it, but does not obscure the first sound; the pulmonic second sound is frequently accentuated.

The organic systolic murmurs in the pulmonic area are much rarer. The harsh murmurs of congenital pulmonic stenosis and acquired pulmonic stenosis have a very limited area and are usually accompanied by a rough thrill. The former condition is accompanied by cyanosis, a frail physique, easy fatigue and early cardiac failure, while the latter may be compatible with reasonably good health and a sense of well-being for many years. In the cases I have seen, the difference between the general condition of the patients with congenital lesions and that of those with acquired lesions is very striking. The nearness of the so-called "valve areas" and the similarity of the murmurs in aortic stenosis and pulmonary stenosis make the differential diagnosis sometimes quite difficult or even impossible. Other physical findings and history must be used to their fullest extent in such cases.

Cardiorespiratory murmurs are most commonly heard along the left border of the heart. They are usually systolic in time, very rarely diastolic. They are due to the pressure of

the heart against the lung during systole or to the squeezing of air from the lung during the contraction, or to old adhesions between the pleura and pericardium. Sometimes a history of pneumonia or a healed tuberculosis may explain it. Other physical signs will of course be absent and if it can be determined that the murmur is respiratory it has no importance. In like manner obesity, upward pressure of the diaphragm or tumors of the chest may be the cause of systolic murmurs. Over the base of the heart, aneurysm, dilatation, constriction from without, or any deformity, may cause murmurs in the great vessels as well as in the peripheral.

THE DIASTOLIC MURMURS

The diastolic murmur is more difficult to hear than the systolic murmur and of much greater importance. It is occasionally functional without valve involvement when changes occur in the aorta in hypertension and arteriosclerosis. It is practically never an unimportant murmur, as is the systolic in numerous instances. It occurs in two organic conditions, aortic regurgitation and mitral stenosis.

In aortic regurgitation the murmur is soft and blowing; it may be heard over the aortic area or over the entire precordium, but it is usually of greatest intensity along the left border of the sternum at about the third and fourth interspaces. Because it occupies all of diastole it usually entirely obscures the second sound. In well-marked cases of aortic regurgitation there is lateral and downward enlargement of the heart with the cardiac impulse in the sixth interspace; throbbing of the carotids with head-nodding; pulsation of the retinal vessels; the characteristic Corrigan or "waterhammer" pulse; often a normal or high systolic blood pressure with a very low or almost absent diastolic pressure, giving the typical high pulse pressure of the lesion; throbbing of the femoral, iliac, posterior tibial and dorsalis pedis vessels with the typical sharp systolic shock known as the "pistol shot," heard with the stethoscope over these vessels, especially the femorals and iliacs; not infrequently over the iliacs systolic and diastolic murmurs are heard—known as Duroziez's sign. In most well-marked cases, especially with a high pulse pressure, there is a capillary pulse but a little care must be used in eliciting

this sign, as it may occur in some who have not aortic regurgitation, or even in normal individuals. The best method is to rub the forehead with a tongue depressor until it is hyperemic and as the redness begins to disappear the pulse may be seen as a rhythmically recurring blush. Do not stand too near the patient if you wish to see it to the best advantage.

Sometimes patients have entered the hospital with many of the physical signs of aortic regurgitation but the murmur does not appear until there has been a rest in bed for several days, when, with increased muscle tone, it appears with its usual qualities.

The earliest murmur of mitral stenosis is mid-diastolic, soft, blowing and often difficult to hear. In every case with an apical systolic murmur, especially if of sufficient duration, intensity and persistence, the mid-diastolic murmur should be carefully sought. All murmurs vary with the amount of muscle force in the heart, with the cardiac rate and with the rhythm. So the early soft murmur may be mid-diastolic where the rate is normal and the rhythm fairly regular; sometimes it may be late diastolic or it may be early diastolic, especially when it precedes and merges into the rough diastolic, ending in a sharp first sound, the murmur often spoken of as presystolic. Years ago the presystolic was considered the determining diagnostic sign of mitral stenosis—often the disease was not recognized until this rough, sometimes called crescendo, murmur was heard. It is accompanied by a thrill, a heaving cardiac impulse and by a radial pulse small in volume and of low tension. The thrill is also presystolic but too much effort need not be expended in determining its exact time—if it is fairly marked and accompanies a presystolic murmur, that is enough. It is agreed that the murmurs of mitral stenosis are caused by left-auricular systole and therefore they are soft diastolic at first, but as the warping and stenosis of the valve advance while the muscle force of the auricle remains fairly normal, the blood in passing through the narrowed opening causes a rough murmur and a palpable vibration. This roughness often disappears with dilatation of the auricle and with the onset of marked arrhythmia; in auricular fibrillation especially, the murmurs may be entirely absent or heard only in the longer diastolic spaces. When a blowing diastolic

murmur is audible at the area of cardiac impulse there should be little doubt about its significance—it is probably organic. Aortic regurgitation occurs at a valve opening which is concerned with the second sound of the heart and the regurgitant blood stream obscures the sound of its closure. The diastolic murmur of mitral stenosis occurs at a valve unrelated to the second sound, therefore is unobstructive to it. The shape of the heart, the position of the cardiac impulse, the character of the pulse, the sounds in the blood vessels are all quite different in the two conditions.

Sometimes young persons with thin chests, who are nervous about being examined, especially by a new physician, may present what appears to be a vibratory murmur accompanied by a thrill which later entirely disappears. Another condition producing a relative mitral stenosis without actual damage to the mitral valve is probably left-ventricular dilatation.

Two conditions seem to produce a relative mitral stenosis, more commonly aortic regurgitation and less frequently dilatation associated with adherent pericardium. Several theories have been advanced over the years to account for relative mitral stenosis. The time relations and other characteristics of the murmur are the same as in organic mitral stenosis, except that the murmur is usually less intense and is unaccompanied by a thrill. When the mitral diastolic murmur just described accompanies aortic regurgitation it is known as the Austin-Flint murmur. In cases of organic mitral stenosis associated with aortic regurgitation, the lessened volume of blood caused by the stenosis often has a modifying effect upon the Corrigan pulse but this is not the case with a merely functional mitral diastolic murmur.

Pulmonary regurgitation is very rare but its murmur has all the characteristics of the diastolic murmur of aortic regurgitation. While the latter is best heard along the left border of the sternum, the murmur of pulmonary regurgitation is equally loud or may be louder in the pulmonic area, but it is unaccompanied by signs in the peripheral circulation so characteristic of aortic regurgitation. Radiographic studies of the lungs for pulsations and abnormal right-axis deviation in the electrocardiogram will help to differentiate the pulmonary regurgitation murmur from the aortic. Mitral

stenosis, by causing increased *pulmonary tension*, and therefore dilatation of the pulmonary artery and valve ring without valve pathology, may cause pulmonary regurgitation and the diastolic murmur thus produced is known as the Graham Steell murmur.

Other causes which must be considered are acute or chronic endocarditis of the valve as illustrated by a case seen a few years ago with a gonococcus involvement of the pulmonary valve; chronic disease of the lungs; sometimes extended patency of the ductus arteriosus and congenital defects which give rise to regurgitation as a sequel of stenosis.

PERICARDIAL FRICTION RUBS

We have heard physicians debating the differentiation between double murmurs and the pericardial friction rub. The rub may be mistaken for murmurs, especially if the sound is soft, faint, and audible only in systole, where it is often heard much better, because contraction is more active than filling. If you listen very carefully during diastole you will hear an exactly similar sound, although at times much fainter. The unmistakable pericardial friction rub is rough and rasping during systole and of similar quality during diastole, and may be accompanied by a palpable thrill. Another important point is that pericardial rubs often change their position in the precordial area from day to day, as organic murmurs never do. When the friction rub is present it may obscure valve murmurs. Let me illustrate what I mean by the change in position of the pericardial rub, by recalling an incident reported some years ago. The quest for a case of aortic stenosis in the hospital resulted in my being shown a twenty-seven-year-old male patient convalescent from acute rheumatism and having the condition I was in search of, according to the diagnosis. The man looked well and said that all of his symptoms had subsided. On listening over the aortic area, a rough, grating, systolic murmur was heard and also a very faint murmur of similar quality in diastole. There were no cardiac nor circulatory signs indicating aortic stenosis or regurgitation. In the absence of confirmatory signs of valvular disease and taking into account his recent attack of acute rheumatism, a pericardial friction rub seemed probable. Two days later the

SIGNIFICANCE OF HEART MURMURS

rough systolic sound and the fainter diastolic were heard at the third interspace to the left of the sternum, the following day over the fourth and by the fifth day they were audible just above the cardiac impulse and then disappeared. In other words, there was no aortic stenosis, but there was pericardial friction rub. During acute infections, especially rheumatic fever, the precordium should be explored for friction sounds, knowing that they may be very transitory. Once heard, if only for a brief period, we should make a search for valve murmurs, since we know that myocarditis, endocardium and pericardium are probably all involved, though in varying degrees.

TO-AND-FRO OR CONTINUOUS MURMURS

The commonest and least important of the continuous murmurs, one long known to physicians, is the venous hum of the neck. It is loudest at the base of the right side, less so on the left, is heard in many normal individuals, especially children, and is important to consider only because it may be transmitted to the base of the heart, where it may give rise to an erroneous diagnosis of aortic regurgitation, especially if the diastolic part of the hum happens to be prominent. In the absence of other signs of valvular lesions will disappear with the diagnoses.

Patency of the ductus arteriosus gives a see-saw murmur, louder in systole and best heard in the first or second interspace to the left of the sternum. Probably no other murmur has this continuous, grinding character throughout the cycle, and if it can be distinguished from the venous hum of the neck and arteriovenous aneurysms it is usually monomelic.

SUMMARY

Murmurs are merely a part, sometimes a very small part, of the complete cardiac and circulatory examination.

Medical history should be thorough and searching, and aid in estimating the importance of any murmur.

During the course of acute infections, especially rheumatic fever, there should be no haste on the part of the physician attendant to reach a conclusion concerning a murmur. Convalescence may entirely change the cardiac findings.

If a murmur is heard during a routine physical examination, some information about it should be given to the patient or his relatives, because if it is passed without comment another physician at a subsequent examination may unduly alarm the patient and you will be considered remiss.

The systolic murmur is much commoner than the diastolic, easier to hear but often more difficult to interpret. The systolic murmur is more often functional than any other. The duration and intensity of a systolic murmur should be carefully studied. If the evidence points to a functional murmur the patient should be seen at regular intervals to substantiate the opinion, because it is well known that many systolic murmurs which are classed as benign because there is no other evidence of cardiac inefficiency, are actually the earliest indication of serious valvular pathology. The louder systolic murmurs are usually associated with organic cardiac disease.

If the physician keeps the normal physiology of the valves in mind he will not have to burden his memory with the time and character of murmurs produced by valve pathology.

Simple murmurs do not require treatment, while organic ones demand whatever the cardiac inefficiency requires.

CLINIC OF DR. EDWARD S. EMERY, JR.

PETER BENT BRIGHAM HOSPITAL

THE DIAGNOSIS AND MANAGEMENT OF THE CHRONIC OBSTRUCTIVE TYPE OF PEPTIC ULCER

To treat successfully a patient with a peptic ulcer and chronic obstruction, one should know when an obstruction is in fact chronic and when surgery is indicated for its alleviation.

Ulcers may produce all grades of obstruction. There is the transient obstruction, which is obviously the result of a pylorospasm. Then there is the permanent type, which shows little fluctuation but may progress over a series of years. This kind of obstruction can be divided arbitrarily into two categories; the one which subsides on a good medical régime and the one that does not. A word should be said at this place about the cause of the more permanent types of obstruction. It has been taught for years that the obstruction which responds to medical treatment is the result of spasm and edema and that the other group is produced by a cicatrization of the pylorus. This teaching seems to have been based on pure reason without observation, for there is really very little, if anything, to substantiate the idea of a true cicatrization. In a recent conversation with a pathologist of wide experience, he stated that he had never seen a cicatrized pylorus due to ulcer. The late B. W. Sippy used to teach that retention disappeared on his treatment at the end of three months in 50 per cent of the cases and at the end of nine months in 85 per cent. Therefore, it is reasonable to believe that obstruction results from spasm and hypertrophy of the pylorus in most, if not all, of the cases. This complication should ultimately respond to medical treatment in virtually all cases, if

the treatment is persisted in thoroughly enough and long enough. Hence the former principle of treatment, that obstruction requires surgery because of the nature of the condition, does not seem to be correct. Surgery should be resorted to when it will relieve retention more easily than medical treatment, and thus save the patient time and spare him an adherence to a very strict and long continued régime.

The decision of when to use surgery may be decided on one or more of the following aids to diagnosis: (1) The roentgenographic findings. (2) Evidence from gastric aspirations of undue retention. (3) A history of obstructive symptoms. (4) The failure or otherwise for the obstruction to respond to medical treatment. In evaluating the use of the x-ray in the diagnosis of obstruction, one must remember that this method of investigation merely reveals visual evidence of what seems to be taking place in the stomach. The roentgenologist deduces from the available evidence whether or not an obstruction is present. One of his aids to diagnosis is the presence of retention, the amount of which is usually expressed in percentage of the total amount of barium ingested. Retention alone is not evidence for obstruction because complete retention may result from a lack of peristalsis. This situation occurs most frequently under the influence of a headache or emotion, frequently precipitated by worry over having the roentgenographic study.

The type of peristalsis is a further aid to the roentgenologist. Increased resistance to the outflow of the gastric contents produces more work for the stomach with a resulting hypertrophy of that organ. Therefore, marked grades of stenosis are accompanied by deep peristaltic waves. The presence of a large retention associated with increased peristalsis usually is good evidence for a so-called "high-grade" obstruction. However, since all degrees of hypertrophy may be encountered, and since hyperperistalsis in the absence of anything more than pylorospasm can occur, it is not always easy to differentiate between the two. In such situations a history of obstructive symptoms is useful evidence although not infallible. Some patients vomit more readily than others. It is not uncommon to find individuals with almost complete stenosis, who have never vomited, in contradistinction to others

who have been vomiting frequently without any chronic obstruction. The latter patients frequently suffer from an acute pylorospasm which subsides quickly on medical care. Enough has been said to show that a single roentgenographic examination may not tell much of practical value concerning the presence or the degree of obstruction. Except in those cases with a high-grade obstruction a second roentgenographic examination should be used to check the first.

As will be seen later, a knowledge of the amount of obstruction is important in deciding when to use surgery. Therefore, one is interested particularly in how the stomach handles ordinary food. Its behavior toward food is not answered by the usual roentgenographic examination. The usual barium meal is of a liquid or semisolid consistency, and the stomach behaves differently with liquids than with solids. Also the barium is an unusual substance to enter the stomach. It is a heavy mixture, the solid portion of which settles out quickly. It may flow rapidly through a narrowed pylorus or plug effectively this opening, depending upon the shape of the stomach. One would expect that the results from a barium meal might differ from an ordinary meal, and this has been found to be true.

A comparison of the roentgen and clinical evidence for retention in 266 patients seen at the Peter Bent Brigham Hospital showed an agreement between the two methods in 53 per cent. The closest agreement occurred with those patients which showed a large residue by the x-ray. Seventy-one per cent of those having from 30-60 per cent retention by x-ray also showed clinical evidences of retention, whereas, the results agreed even better when the retention by x-ray was over 60 per cent. Ninety-one per cent of the latter showed clinical retention. The 9 per cent showing a large roentgen retention but no clinical obstruction were the cases with reflex spasm due to headache, nervousness, etc. Disagreement between the results obtained by the two methods occurred almost entirely in the patients in which smaller residues were observed under fluoroscopic examination. These figures show that a single roentgen examination is not an accurate measure of how well the stomach can handle food.

Recognition of this fact is important, if one is to afford

suitable treatment for these patients, because clinical studies demonstrate that sole reliance on the x-ray does not give the best criteria for treatment. At the Peter Bent Brigham Hospital medical treatment was effective in only 38.6 per cent of the cases in which the gastric aspirations and the history agreed with the roentgen findings, whereas, it was of benefit in 68.2 per cent of the cases in which the roentgenogram alone suggested retention. The retention in many of the latter group was doubtless the result of temporary spasm. It is evident from this data that reliance on roentgen evidence alone will result in subjecting an unnecessarily large number of patients to surgery.

This difficulty can be offset by utilizing the final method of study that was mentioned, namely, putting the patient on a good medical régime. This medical treatment should be effective in overcoming the known causes of irritation, namely, the hydrochloric acid and the effect of prolonged gastric residues. This is accomplished most satisfactorily by a Sippy régime with gastric lavage every night and again in the morning, if there is found to be an increase in the fasting contents. This treatment should be continued if a large retention subsides quickly. The persistence of a large retention after a week to ten days usually means a marked obstruction and surgery might as well be used at once. Meanwhile, no time has been wasted because these patients do better if they are prepared with frequent gastric lavages.

Medical treatment should be continued for six weeks to three months on patients with moderate retention. Six weeks is a minimum period on which to gauge the effect of treatment, because it seems to require this length of time for moderate degrees of pylorospasm to subside. In fact, the first effect of medical treatment may be an increase in retention which later subsides. This phenomenon is caused in all probability by a decrease in excessive peristalsis before a decrease in obstruction takes place.

Three months usually is long enough to decide whether the obstruction is responding in a satisfactory way to medical treatment. Although most cases should respond ultimately, if one persists in treatment long enough, usually it is better to use surgery after three months, if very definite improvement

has not occurred. Some guide as to what constitutes a satisfactory response is given by the results obtained in this clinic. It has been found that the end-results of treating a gastric retention under 40 per cent is similar with medical or surgical therapy. Because this figure was obtained before patients had had any treatment, it is wiser to use a lower figure after medical treatment has been used. Hence, it is good practice to operate upon a patient who still has a 30 per cent retention by the x-ray after three months of good medical treatment.

This gives us a plan for treating ulcer patients with retention. One should employ surgery for patients with a gastric retention of 40 per cent or over, who have evidence of a long-standing pyloric obstruction, as shown by deep peristaltic waves due to hypertrophy.

Patients with a retention of 40 per cent or over but without evidence of hypertrophy by the x-ray should have a preliminary trial with medical treatment.

For the patient with a large original retention of 60 per cent or over, which may be due to either temporary inhibition of peristalsis or to obstruction, a period of seven to ten days on medical treatment usually is sufficient to decide which kind of treatment to use.

For all other patients with a retention of 40 per cent, medical or surgical treatment give equally good results.

The following illustrative case demonstrates what can be accomplished by careful medical treatment:

J. J. O., a fifty-eight-year-old rent collector, had had symptoms of ulcer for twenty years, when first seen in 1929. At the time he consulted us he was troubled chiefly by the rumbling of gas and fulness. He had not vomited. Physical examination was essentially negative. A roentgen examination reported a 90 per cent retention with an obstructive type of peristalsis. He was referred to the hospital wards and placed on a Sippy régime with aspirations each night. After four weeks of this treatment, the stomach was hypertonic, showed vigorous peristalsis, but the residue had decreased to 5 per cent. One month after discharge from the hospital the stomach still showed vigorous peristalsis and a 10 per cent residue. At this time he was given the choice of surgery or of continuing with daily aspirations, but he preferred to go on as before. He remained on a Sippy régime with daily aspirations for another year. He was then obtaining 750 to 900 cc. of gastric contents each night. Because the ulcer had given no symptoms for a year, the Sippy treatment was stopped, and the patient was put on a carefully supervised list of foods with five feedings a day. He continued this dietary treatment with aspirations every night for the next two years. For the last two years he has aspirated

only occasionally. The retention has steadily diminished until now he aspirates only 200 cc. three hours after supper, and there was no retention by x -ray at the last examination.

Most patients would prefer surgery to undergoing such a long and vigorous medical treatment, but the case illustrates that marked obstruction will respond to medical treatment and it is, therefore, always justifiable to determine the effect of medical treatment on obstruction due to ulcer before instituting surgery.

FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY
HOSPITAL AND THE DEVELOPMENT OF MEDICINE AND THE
COLLIS P. HUNTINGTON MEMORIAL HOSPITAL, HARVARD
UNIVERSITY

THE CLINICAL IMPORTANCE OF THE SEQUENCE OF EVENTS IN BONE MARROW FAILURE

ABNORMALITIES in the peripheral blood picture must be interpreted with caution and with due regard for certain physiological principles and clinical facts. In both hospital and private practice we not infrequently encounter patients with unusual blood findings which reflect but poorly the true underlying pathological condition, which may indeed be due to abnormalities in systems other than the hematopoietic. Blood pictures varying but little from the normal may be associated with the early stages of the most fatal blood diseases and, on the other hand, marked changes may be but temporary and not due to any fundamental or serious bone marrow dyscrasia.

The following cases illustrate certain points in diagnosis and prognosis which may be of interest to the clinician.

Case I.—A married woman* of thirty-five years had been taking $1\frac{1}{2}$ grains of dinitrophenol intermittently for the past year. During the two weeks prior to admission to the hospital she had taken approximately 21 grains of the drug and had lost 7 pounds in weight. Six days prior to admission she had an attack of acute tonsillitis, for which she was treated symptomatically. On the sixth day of this illness she appeared definitely worse and was taken to the hospital on May 14, 1935. Then, for the first time, her blood was studied. The white blood cell count was 900 per cubic millimeter; the red blood cell count 3,320,000; the hemoglobin 62 per cent. Examination of the blood smear

* I am indebted to Dr. Stanley Imerman of Los Angeles for permission to cite this case.

showed 94 per cent lymphocytes and 6 per cent eosinophils. The platelets were slightly decreased. Her temperature was 104° F.; the pulse 130; the respirations 20. Both tonsils were enlarged, ulcerated, and covered with a grayish membrane. The soft palate, uvula and pharynx were acutely inflamed. Cultures for the throat were negative for diphtheria bacilli. The urine contained a trace of albumen, an occasional cast, and a few red blood cells. A diagnosis of agranulocytosis secondary to dinitrophenol therapy was made and the patient immediately started on pentnucleotide, 10 cc. intramuscularly four times a day. This she bore without untoward reactions. In addition 3 cc. of liver extract were given each day. Appropriate symptomatic treatment was, of course, continued and all dinitrophenol medication stopped.

From a clinical point of view she remained very ill, semiconscious and rational, but on May 18, four days after admission, the white blood cell count had risen to 1700 per cubic centimeter, and there were found in the smear 19.2 per cent polymorphonuclear neutrophils, 16.2 per cent monocytes, 61.2 per cent lymphocytes, 1.5 per cent eosinophils, and 1.9 per cent unclassified cells. The throat condition seemed definitely improved. The pentnucleotide was continued in full doses.

Three days later, on May 21, the patient's clinical condition was greatly improved and the temperature dropped to normal. The white blood cell count had risen to 4000 per cubic millimeter and the neutrophils were 35 per cent, but coincidentally the platelets had fallen to 30,000 per cubic millimeter. The red blood cell count was still 3,300,000 per cubic millimeter. Many petechiae were noted scattered over the body and in the mucous membranes. The platelet decrease, however, proved to be of an evanescent nature; for five days later the blood contained a normal number of these elements and there was no further hemorrhagic tendency. Moreover, the white blood cell count had then risen to 12,000 per cubic millimeter, and the polymorphonuclear neutrophils to 65 per cent. Pentnucleotide was then discontinued.

But by this time, two weeks after entry, the red blood cell count had fallen to 2,900,000 per cubic millimeter, and the hemoglobin to 56 per cent. A week later the red blood cell count had fallen still further to 2,500,000 per cubic millimeter. This slowly developing anemia, together with at least temporary marked reduction of platelets with attendant hemorrhages, aroused the suspicion that the condition was in reality a true aplastic anemia or pancytopenia and the fear was expressed by some that a fatal termination might be looked forward to. Such, however, was not my opinion. It may correctly be assumed in this instance that the dinitrophenol was the cause of the existing blood dyscrasia. It may further be assumed that on or about May 5 the toxic action of this substance had reached a sufficient degree to destroy or suppress, in large parts at least, the existing active bone marrow. The first outward and visible effect of such an action would be the partial or complete disappearance of the polymorphonuclear neutrophils, whose natural life in the peripheral blood is probably a matter of a few hours or at most a few days. This finding, together with the recognition of its significance, resulted in the withdrawal of the causative agent and the initiation of those measures which at present seem most likely to result in a stimulation of the granulocytic elements of the bone marrow. It is a matter of record that these cells did reappear in considerable numbers in less than a week. There was, therefore, tangible and unequivocal evidence that the bone marrow was recovering, at least in so far as the granular series was concerned.

With the red cell series the situation is quite different. The average life of a red cell in the peripheral blood is generally conceded to be from three to six weeks. The rate of formation of new red blood cells proceeds slowly; never with the dramatic suddenness with which white cells may be replaced. Under these circumstances it must be obvious that if a bone marrow is virtually wiped out by some toxic agent on a given date, anemia of moment will not make its appearance in the peripheral blood for several weeks. If, in the meantime, the noxious agent has been removed, if such measures as may be regarded as favoring bone marrow recovery have been instituted, and if there become manifest certain signs of recovery of the bone marrow, such as an increase in the white blood cell count, then it may safely be assumed that the anemia, such as developed in this case, is the natural and inevitable result of the original insult and need not necessarily be regarded as indicating the development of a further or more serious disease. Transfusions of blood under these circumstances are not, in my opinion, indicated unless the patient be in actual danger from the anemia *per se*. They may do more harm than good and severe reactions are not uncommon.

In late May, two and a half weeks after entry, the white blood cell count had risen to 13,000 per cubic millimeter and the neutrophils to 65 per cent. The temperature, which had been normal for many days, again rose. The patient developed a dry, hacking cough and complained of pain in the left upper chest. x-Ray films showed what appeared to be pneumonia in the left upper lobe. As time passed it became increasingly evident that the process was indeed a pulmonary abscess. For this complication general supportive and symptomatic treatment was instituted. In a month the abscess under this conservative régime, was but half its original size. In another month it had entirely disappeared. In the meantime, the red blood cell count rose to a normal figure and by July 13, eight weeks after entry, all abnormalities of the blood had disappeared and the patient was clinically well.

The lesson that such a case teaches is that the development of the various signs of bone marrow insufficiency become manifest at varying intervals after the original provocative injury; leukopenia in a few days, thrombocytopenia probably in a week or so, anemia not for several weeks. The natural history of recovering (or failing) bone marrow must be carefully considered in any diagnosis or prognosis.

The implications derived from such considerations are

broad. The late development of anemia following the action of a toxic substance on the bone marrow does not necessarily imply that some new and unexplained insult has resulted. In a similar manner the absence of anemia during the early stages of a blood disease does not necessarily rule out those conditions commonly thought of as being associated with profound and progressive anemia. This latter point is illustrated by the following case.

Case II.—On April 22, 1935 I saw with Dr. H. T. French and Dr. C. C. Stewart of Hanover, N. H., a boy fourteen years old. He had always been strong and well and led a normal and active outdoor life. The only fact of any possible moment in his past history was that in infancy his diet had, for a short while, been definitely inadequate and unbalanced. For several weeks prior to admission to the hospital he had seemed somewhat lazy and somnolent; he lacked initiative and was inattentive. On April 15 he had a severe headache and complained of anorexia, nausea, and occasional vomiting. There was no abdominal pain. On admission his temperature was 103° F. This gradually fell to normal in three days, only to rise again to 102° F. on the fourth day. On examination at this time (April 22) he was found to be a well-built, strong-looking boy, a little drowsy and listless, but rational and cooperative. There was a definite but minimal bilateral horizontal nystagmus. The remainder of the physical examination was essentially normal. There was no lymph node enlargement in any region. The spleen could not be felt even on deep inspiration. There was no tenderness, spasm, or masses in the abdomen. Neurological examination was normal except for a questionable stiffness of the neck. Neither lumbar puncture nor x-ray films of the chest revealed any abnormalities.

The red blood cell count was 4,800,000 per cubic millimeter; the hemoglobin 90 per cent; the white blood cell count 2500 per cubic millimeter with 90 per cent normal lymphocytes, 8 per cent polymorphonuclear neutrophils and 2 per cent monocytes. The neutrophils showed no evidence of toxic degeneration such as are so frequently seen in the presence of an infection. The platelets were normal in number and appearance.

The condition was, therefore, essentially one of unexplained leukopenia, neutropenia, and fever. Idiopathic agranulocytosis seemed out of the question. It is extremely rare at this age. Fever of moment in this disease is due to infection secondary to the leukopenia and this infection is almost always obvious on careful examination. No such infection was in evidence. Furthermore, no drugs had been taken which might logically have been regarded as productive of the leukopenia. Leukemia is usually accompanied by progressive anemia, bleeding and the finding of abnormally young cells in the peripheral blood; these features are almost constant once fever has set in. Yet it must be recognized that in leukemia of children there may rarely be but moderate departure from the normal white blood cell picture and, as pointed out above, anemia of any great degree does not develop under such conditions until after the lapse of several weeks. A diagnosis of leukemia in this case, therefore, could not be summarily discarded. It seemed, however, extremely unlikely and was not at any time seriously entertained. There remained the possibility of some obscure infection of uncertain nature and unknown locus. Such

a diagnosis would not advance our practical knowledge of the case in any way as long, that is, as its locus remained unknown.

The boy continued to run an irregular fever for three weeks. During this time the white blood cell count ranged from 1500 to 3000 per cubic millimeter and the neutrophils from 10 to 28 per cent. At no time were abnormal or immature white blood cells seen in the smear. Gradually his general condition improved. The fever abated. The blood picture became normal and he returned home apparently well on May 10, approximately four weeks after admission to the hospital.

He remained well until May 25 when once more his temperature rose, this time to 104° F. The initial symptoms of drowsiness reappeared and once more nausea, anorexia and vomiting occurred. Coincidentally the white blood cell count fell to 900 per cubic millimeter and the differential count revealed 100 per cent lymphocytes, all of them normal. The red blood cell count had fallen to 2,500,000 per cubic millimeter and the hemoglobin to 50 per cent. A new element, anemia of unexplained origin, had appeared. The physical examination was still essentially normal. There was no enlargement of the lymph nodes or spleen. Examination of the abdomen was negative. The elevated temperature continued and on June 3 reached 105° F. At this time there was definite soreness of the throat and the gums were found to be swollen and spongy. Retinal hemorrhages appeared in both eyes. A third element, the hemorrhagic diathesis, had appeared. The red blood cell count had fallen to 1,600,000 per cubic millimeter.

Now the significance of the anemia here would appear to be quite different from that in the first case. In that instance there was a definite and removable etiological agent which produced a sequence of events from which anemia was to be expected to develop even in the face of evidence of recovery on the part of the other blood elements. In the case of the boy we were dealing with a leukopenia of unknown origin and fluctuating course to which the subsequent development of anemia added further evidence of a serious bone marrow disease. It seemed evident, once anemia and thrombocytopenia had developed, that unless some definite and logical cause for the hematological abnormalities could be found one would have to assume a primary and probably irremediable bone marrow disorder.

Nevertheless, the temperature once more gradually came down to normal and there was definite clinical improvement. The white blood cell count rose to 2000 per cubic millimeter and the neutrophils to 24 per cent. The anemia, however, persisted in spite of intensive treatment with iron and liver extract. After this period of improvement the temperature again rose precipitantly, and the red blood cell count fell to 750,000 per cubic millimeter. Not the slightest evidence of regeneration of the red cell series could be found. The white blood cell count dropped to 500 per cubic millimeter, all granular cells disappeared, and the boy died in early July, three months after the initial symptoms.

We are indebted to Dr. R. E. Miller of Hanover, N. H. for a study of the necropsy material. The positive findings were few. There was a chronic appendicitis with loss of the mucosa and masses of bacilli, some in phagocytes, in the superficial tissue. In addition, there was a slight periportal fibrosis of the liver, probably secondary to the appendiceal infection. From the appendix a bacterium of uncertain nature was recovered. The bone marrow was throughout aplastic and cell poor. There was no evidence of leukemic infiltration. On microscopical examination there was obvious a

marked hypoplasia of all the formed elements. Such few cells of the granular series as were present appeared normal. Erythropoiesis was scanty. There was no evidence of invasion by any malignant tumor.

While the case cannot be reconstructed with complete assurance, it would appear most likely that a slowly developing pancytopenia was the essential and primary lesion and that coincident with each period of marked neutropenia there was an exacerbation of the existing gastro-intestinal infection. Such an interpretation would be in accord with clinical experience. It may also be argued that the infection was primary and resulted in the pancytopenia, but chronic infection rarely produces such a blood picture when the clinical evidence for this infection is so slight as to be unrecognized during life and when postmortem studies reveal only a relatively mild and localized infectious process. Infection, when overwhelming, produces exhaustion of the bone marrow with evidence in the peripheral blood stream of ineffectual and spasmodic attempts at regeneration. On the other hand, drowsiness, nausea, vomiting and fever are common enough accompaniments of extreme leukopenia and of pancytopenia and it is important to remember that in this latter disease the process does not steadily progress with smooth regularity, but rather by a series of remissions and relapses. It is important, further, to remember that all the formed elements are not simultaneously or equally depressed. As a rule the white blood cells suffer first, the red cell series second and the platelets last, although of course there are many exceptions to this general rule. Moreover, in the presence of leukopenia, even of the most transient sort, any existing infection may advance apace, to subside again as the primary defense against infection, the leukocytes, is reestablished. Taking all the evidence at hand, it would seem most logical to assume the presence of a progressing pancytopenia of unknown pathogenesis with a concurrent and secondary gastro-intestinal infection. In any event, extreme leukopenia and neutropenia in the presence of fever must be regarded as ominous, even though the phenomena may appear to be transient. We should be guarded in our prognosis, even though there be no anemia, remembering, as in the first case, that it takes time for such to develop.

In brief, one cannot or should not interpret the whole

clinical picture from a cross section of the blood abnormalities at any one time. The natural history of the failing and the recovering bone marrow must be taken into consideration. The fluctuating and remitting course of the early stages of serious bone marrow disorders must be recognized. No matter how striking the blood changes are the condition may be remediable; no matter how insignificant they may seem they may reflect the onset of a fatal condition.

FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY
HOSPITAL AND THE DEPARTMENT OF MEDICINE, HARVARD
MEDICAL SCHOOL

PAIN IN THE REGION OF THE HEART

Introduction.—We shall deal in this paper with pain in the region of the heart that is not angina pectoris. The difference between pain or distress in the region of the heart and angina pectoris will not be discussed, because descriptions of angina pectoris can be found in many textbooks and a repetition is not needed.

The pain or distress in the region of the heart with which we are concerned not only is not angina pectoris, it is nearly always not a symptom of any organic disease, and is usually definitely neurotic. This statement will surprise very few. Physicians generally are familiar with the fact that pain in the region of the heart, even when it is of great severity, may be a neurosis. Nevertheless, we find that such pain, when encountered clinically, is so disturbing that it frequently causes physicians, particularly when they have it themselves, even though they are technically familiar with cardiac neurosis, to believe that the pain must be an indication of organic heart disease when it is not. The need for correct diagnosis is clear. There is a vast difference in the treatment of cardiac neurosis and cardiac disease. We could cite many case histories to show that errors of judgment in either direction may be disastrous. In this connection, we find that minor errors in diagnosis and treatment are often caused by a failure to appreciate that neurotic pain in the region of the heart may occur coincidently with organic heart disease. In fact, neu-

roses are proportionately higher among those who have organic heart disease. Cardiac cases naturally have their attention directed toward and their anxiety aroused by the action of their hearts. Often, for example, a patient with mitral stenosis consults a specialist not because of symptoms due to the mitral stenosis, mitral stenosis may give no subjective symptoms whatsoever, but because the patient, knowing of the heart disease and its dangers, develops neurotic symptoms suggesting to all concerned an alarming situation. We also believe that, in spite of its importance, cardiac neurosis has been neglected. We seldom find it demonstrated in clinics or discussed at scientific meetings. It is a confusing topic and, therefore, perhaps avoided. We believe a discussion of it is in order.

Terminology.—People suffering from vague symptoms, including pain in the region of the heart, which we nowadays definitely label neurotic, symptoms which tend to be confused with symptoms of organic heart disease, have long been recognized. Terminology has contributed to the general confusion concerning them. The inept term “functional heart disease” was formerly used to classify these cases and indeed we find it still used at times. During the World War these cases were vigorously studied, and this term was abandoned. The names “soldier’s heart,” “disorderly action of the heart,” “effort syndrome” and most apt of all, “neurocirculatory asthenia,” were applied to them. We will use this last term for the remainder of this article, abbreviating it to its initials, N. C. A. This term is generally somewhat familiar.

A distinction has been made by some observers between “cardiac neurosis” and “N. C. A.” on the basis that in the former there is no objective evidence of cardiovascular disturbance. We believe it is inappropriate to try to make such distinction since our cases grade evenly from one class to another and individuals change their symptoms so that one would have to reclassify them from time to time. We would refer to N. C. A. including those patients who would be called “cardiac neurosis” by those who wish to attempt a distinction.

N. C. A. Among Soldiers.—Study during the war was forced by military and economic necessity. In England alone, at one time, 30,000 soldiers were in hospital supposedly com-

pletely disabled by N. C. A. Physicians found themselves unprepared for these vast numbers of disabled young men with symptoms referable to the heart. The disorder did not resemble clearly anything with which they were familiar in civil practice.

In brief, the disturbance was as follows: soldiers who had it typically found themselves unable to carry on because of exaggerated feelings of extreme fatigue; they fell out of line of march and dropped at drill. Though the symptoms differed in individuals, in general they complained of stabbing or tearing pains at frequent intervals, usually below the heart, rarely throughout the chest or down one or both arms. Their hearts raced often at a terrific rate, sometimes more than 150 beats per minute. If exercised on a flight of steps, or by 100 hops, their pulse rates did not return to within 10 beats of the preexercise rate after a two minute rest; they thus showed a poor response to effort. Their blood pressure might be unobtainable when they first stood up, but within a few seconds or minutes would climb to a high systolic level, often with a relatively low diastolic level. Some fainted suddenly and remained unconscious for as long as twenty minutes. They trembled so that some could not stand at attention, and had a sense and appearance of anxiety, of "impending calamity." They were breathless on slight exertion and spoke of a sense of suffocation; tachypnea was the rule even at rest. It was noted that their hands, feet and ears tended to be cyanosed, their extremities were cold and they sweated freely. Of course "myocarditis" was the first diagnosis considered. But direct examination of the heart showed no familiar signs of heart disease in the vast majority of cases and it was found that rest was bad for them while exercise helped the majority of them. After a six weeks' course of graduated exercises and drill, roughly 20 per cent of these soldiers seemed able to return to full duty, 20 per cent appeared completely disabled, while the remainder could carry on some degree of duty. Furthermore, these individuals never developed heart failure, no matter how breathless or exhausted they became. No matter how severe the heart pain they never died. So myocarditis as a cause of the symptoms had to be rejected.

Hyperthyroidism was clearly suggested by some of the

symptoms—rapid heart, tremor, increased fatigability. But the patients never developed clear signs of toxicity referable to the thyroid gland, and this possibility was also rejected.

No disease appeared to be closely associated with the condition. The most that one could say was that the incidence of chronic infections, in particular tuberculosis, was somewhat higher among these N. C. A.'s than in the general population. To be sure, N. C. A. symptoms in some cases occurred for the first time or were aggravated by *convalescence* from acute disease or injury. So the effect of organic disease or physical trauma in initiating the symptoms could not be ignored even though it was clear that organic disorders or their late effects could not account for the great majority of the cases. The symptoms were the same where there was no apparent cause, or when they followed pneumonia, rheumatic fever, trench fever, battle wounds, shell shock, a drunken debauch, promotion, demotion, or bad news from home.

Five years after the war it was found (2) that 33 per cent were improved or well, 3.2 per cent had become worse. The condition of the remainder was stationary. This must not be taken as a guide for prognosis for N. C. A. in civil life. Any familiarity with the severely disabled N. C. A. soldiers shows the unfortunate fact that they are more secure if they remain disabled. Feeling their inadequacy, they dread to be pronounced well and forced to take care of themselves. Reassurance can have little effect. And indeed one can only reassure them half-heartedly. There is no certainty that they will succeed in being well if they try.

Follow-ups have shown that these N. C. A.'s were good life insurance and operative risks.

N. C. A. in Civil Life.—It was through the study of soldiers that a solid, though inadequate, basis was established for the understanding and handling of patients with N. C. A. encountered in civil practice. For a few years after the war, occasional reports and studies of this condition appeared, but for the past fifteen years it has been seldom dealt with in lectures or medical publications. We are forced to turn to the older descriptions for reference and we do not often recognize in them the condition we now encounter, for individuals who match the wartime cases in severity of signs and symp-

toms are now rarities. This may be because in civil life we rarely have anything analogous to the war as a cause of sudden and tremendous psychic shock among relatively young people and one can usually more readily escape from the severe tensions that do come in civil life. The symptoms of N. C. A. as encountered today are less dramatic and, at the same time, less clear cut than the war cases. Nevertheless, they are often as disabling and sometimes the symptoms are as severe as ever.

The symptoms of civilian N. C. A. are so various and vague that a thorough description would be difficult and undesirable. We find they are best described by illustrative cases presented against the background of their social and economic environment. We will later give such cases. Certain symptoms, however, occur so consistently that we will mention them. Of course, "heart pain": it grades in severity from a merely uncomfortable sensation or consciousness of the region of the heart or of the heart beat to precordial soreness and stabbing or pinching pain, sometimes of great severity. Such pain is by itself strong evidence of N. C. A. A complaint of breathlessness which really consists of sighing or a sense of inability to get enough air in the lungs, is also a clear sign of N. C. A. The precise value in diagnosis of other common symptoms and signs, such as great fatigability, breathlessness, tremor, cyanosis and tachycardia or poor response to effort is much less.

Curious case histories could be given where violent dyspnea or uncontrollable tremor or repeated fainting or complete helplessness from sudden sense of weakness were the outstanding complaints of cases severely disabled and suspected of heart disease, though the symptoms were purely neurotic, and were relieved by proper treatment. But such cases are comparatively rare. The most common outstanding complaint of the N. C. A. today is some degree of pain in the region of the heart.

CASE REPORTS

Case I.—This patient is a forty-five-year-old busy surgeon who married rather late and has 2 small children. His father died of angina. The patient has frequently made a correct diagnosis of cardiac neurosis on his own patients, nevertheless, he reported for examination with a look of despondency and weariness and, placing his hand beneath his heart said, "I'm done. Angina."

He also complained of precarious sleep and a general sense of fatigue and numerous minor symptoms. Physical examination was negative except for a left inguinal hernia. He had had this for a year, shortly before the onset of his heart pain. It had prevented him from exercising, with the result that he had gained greatly in weight and was in "poor condition." He had, however, "always kept putting off an operation." He feared that he would have an embolus and die. He was advised to take a three months' vacation. There was improvement but only for a few months. A year later, he consented to the hernia operation. As soon as he recovered, his symptoms disappeared and he began to engage in active athletics. He has remained well for several years, though on questioning says that he has little echoes of his pain when especially worried. And, like many physicians, believes that eventually he will die of angina. Many do.

Case II.—This is another physician, thirty-two years old, married with one child, who has been engaged in practice for five years, and through unremitting hard work is now succeeding. He has a good family and past history and no vices. He states that "for the past several months, I have frequently had a sharp stinging pain just under my heart, lasting a few seconds. I am sleeping badly. My wind is not as good as it was. I have been staying up late working and have stopped regular exercise during the last 2 years and have gained a lot of weight. I have never had rheumatic fever, but will you listen to my heart?" The examination was negative, and when he had been reassured and put on a proper schedule of hours for sleep, exercise and diet, his symptoms vanished. When asked several years later about these symptoms, he failed to recall that he had had them or that he had consulted one of us.

Case III.—This patient is a healthy, attractive young woman of twenty-seven, the mother of one child. Her husband had left home to develop an artistic talent. He stayed longer than was expected. There were rumors of unfaithfulness on his part. The patient developed disturbing heart pain and consciousness of her heart beat which frequently was very rapid and forceful. There was breathlessness, easy fatigability and sleeplessness. These continued in spite of reassurance and a hygienic régime until she obtained a divorce with a financial settlement and retired with her child to live with her parents. Even then, there were milder recurrences until she was married to another, but since that time she has remained well.

Case IV.—This patient is a psychiatrist of seventy-two years, charming and intelligent, who had lived a successful life without special hardships, illnesses or disasters. He stated that "I awakened frequently this last winter, and am conscious of my heart beating hard at times and of a sense of soreness around the precordium coming and going for days at a time. On occasion, I have the sensation that I am suffocating and desire to take a full breath. I am fatigued. I come to you to see if I have heart disease or a mother-in-law complex." He did not have evidence of heart disease; he did have a mother-in-law, aged ninety-two, who had come to live in his home and who was a source of increasing anxiety, but he also, though past the age of retirement, was continuing his work and lectureship from year to year, while constantly before him was the unexpressed question, "when shall I break?"

The neurotic symptoms disappeared with explanations and he resumed work with comfort. But the inevitable break came without warning a few years later with an entirely different set of symptoms.

Case V.—Again we are dealing with a physician, a teacher and consultant of forty, who has never been sick and states that he is not nervous. There have been no disasters in his life, he has a happy home, several children and is successful in his profession. For a few months, he had noticed growing fatigability and breathlessness at his accustomed tasks and stabbing pains and a sense of soreness around the heart. Physical examination revealed no abnormality. He was reassured and discussion resulted in the idea that he was not getting enough exercise or rest. This was corrected but no improvement occurred. He then gave up smoking, in which he had indulged heavily, and still he was no better. Finally his teeth were x-rayed; three badly abscessed teeth were found and removed, and within three or four days, he experienced complete and lasting relief from his symptoms.

Case VI.—This woman, now over fifty, was seen by one of us ten years ago as the eighth consultant on her case. She was married, had 2 children and her environment was pleasant and easy. She had a normal inheritance except that a grandmother had been a cardiac invalid for thirty years. She herself had been kept out of school for a year when fourteen years of age with "anemia and myocarditis," but otherwise had had no significant illnesses. Her 2 children were born within two years of her marriage. Twenty years ago, following her second and last pregnancy, she began to suffer from frequent attacks of severe stabbing pain over the precordium, together with consciousness of the heart beat. Her heart rate, whenever taken, was found to be 120 beats per minute or over. There was weakness, easy fatigability and breathlessness. In addition, she suffered from vague digestive disturbances. These symptoms had persisted to the date of this examination. Her symptoms were such that she was only able to be up about six hours a day and felt that she had to be driven everywhere she went. She supervised her home and children but could do no work. She had no particular relaxations although she read a good deal. Her life with her husband was apparently congenial.

Her physical examination was quite negative, except for the tachycardia and some acrocyanosis. Treatment proved unsuccessful. A recent report from her family physician stated that her condition is still unchanged.

Case VII.—This patient is a thirteen-year-old girl. Since the death of her father from angina when she was eight years old she and her mother had lived with a grandmother. During this time she has slept with her mother. The patient's catamenia commenced six months ago. Her symptoms extend over this six-month period. She began by disliking school; she trembled, and felt faint and breathless at meeting people. She had soreness around the heart and frequent stabbing pains. Her heart raced at times. She dreamed, dreams of the anxiety type, frequently. She would hardly allow her mother out of her sight. One night, while her mother was attending a club meeting, she experienced an attack of heart pain so severe that a physician was called at once. He told the mother that he feared the child was suffering from rheumatic heart disease and that she would have to remain in bed for an indefinite period of time. Treatment by digitalis, vitamins and heliotherapy was given, but the symptoms became worse. A grave prognosis was given. The mother gave up all outside activities and devoted nearly every moment to her child.

The symptoms increased. There were tantrums, fainting spells, blurring of vision and transient hemianopia. The child had written poems for years; the poems had grown more mature as she grew older. She continued to write, but now the content of her poems reverted to nursery rhymes.

During the six months of her illness the grandmother had scolded the child and mother persistently, advising the mother not to spoil her daughter, to go out more and not to stay home and act as nurse. When the physician was appealed to, he was distinctly apprehensive regarding the child's heart and insisted on complete rest. (The physician, an experienced and able practitioner was not a poor diagnostician. He was faced with a situation which again and again is found alarming by other able men.)

Physical examination of this child was negative. In spite of the severity of the symptoms and the difficulties of the situation, brief but unreserved discussion of the case with mother and patient together was followed by almost complete relief of symptoms and a return to normal living which has lasted for a year.

Discussion.—These above cases are chosen as typical. The essentials of each are found in many others. With the possible exception of Case V, none had any organic disease which could directly cause the symptoms, and all had sound cardiovascular systems. In regard to most of them, factors in their lives producing anxiety states could be readily ascertained, although these factors had not been appreciated by the patients themselves. Thus in one patient, Case I, it was an unsuspected dread of death from a needed but postponed operation; in another, Case III, a disturbance in her relationship with her husband; a third, Case IV, was apprehensive of the breakdown of old age; while a fourth, Case II, was in poor physical condition from overwork and under-exercise and sleep. In Case VII an intricate and demanding attachment to her mother and jealousy for her attentions led to a state of complete invalidism at adolescence. Only in Case VI, the sole one which did not respond to treatment, are the factors producing the psychic disturbance hidden. In handling N. C. A.'s in general, it is not often necessary to resort to the radical therapy of such workers in abnormal psychology as Freud and Adler, but it is by no means wise to dismiss their theories as never applying. In the more serious and resistant cases, such as Case VI, therapy along these lines may offer the only hope of relief. One wishes that this patient (Case VI) had been analyzed.

Focal infection, as in Case V, appears definitely as an exciting cause now and then, and effective treatment is dependent on its removal. But focal infection is not demonstrable in

the majority of instances, and attempts to cure all by finding and removing obscure possible foci of infection repeatedly end in failure.

Thus, the ordinary *wear and tear* and *vicissitudes* of life with their resulting *anxiety* states, *bad habits* of living, and, to some extent, in a few *inheritance* appear as the exciting factors in most cases. N. C. A. may occur at all ages in both sexes, in all social conditions and among those with all degrees of mental ability. These individuals are usually not constitutionally "neurotic" unless we apply this term extremely widely. It is very common among physicians. Most of the patients get well.

The diagnosis of N. C. A. rests on the recognition of the peculiar nature of the described symptoms. It does not depend on the exclusion of organic disease. It is not made by physical signs or tests.

No matter how elaborately we develop routine physical examinations and laboratory tests, the diagnosis of this common condition can only be correctly made from the personal judgment of an enlightened physician. Though in the great majority of cases the diagnosis to an experienced physician is easy; there are occasional cases that make even those who deal with these cases daily wish to shift the responsibility, and that keep us awake nights. We do not often worry for fear we may be overlooking a serious heart disease. Pain in the region of the heart can, of course, be caused by pericarditis. It may in rare instances be caused by pressure from a greatly enlarged heart, though cardiac enlargement as a rule causes no pain. But, aside from these, pain such as we are concerned with is not caused by obscure heart disease. But there are rare, sometimes serious organic diseases, that can give pain in the region of the heart that is not angina and that neurosis may simulate. Following are some of these rare diseases that, in our experience, have caused severe pain in the region of the heart. The principal lesions, not cardiac, *above the diaphragm*, which we have found in our private consulting practice as a cause for precordial pain are: mediastinal, lung and esophageal tumor or diverticulitis, diaphragmatic hernia, pulmonary embolus, and cervical arthritis. *Below the diaphragm*, disease of the stomach, gallbladder, duodenum and pancreas. One some-

times reads of obscure chest pain which is labeled "pleurodynia," as though this was a specific disorder. We have never allowed ourselves to make such a diagnosis. Patients frequently believe and are encouraged to believe that pain in the region of the heart is due to pressure from gas in the gastrointestinal tract. This explanation serves to distract the patient's mind and to relieve apprehension. But it commonly causes cribbing and belching and resort to various remedies, not always harmless. And, sometimes, the result is a real discomfort from gas pressure. We should remember that pain in the region of the heart is nearly always neurotic. Gastrointestinal discomforts are common symptoms among neurotics. Bad habits, cathartics, cribbing, unnecessary dosing are easily induced.

Because of the similarity between the symptoms and signs of N. C. A. and those of hyperthyroidism, the latter condition should always be considered and eliminated, if necessary, by a basal metabolic rate determination. It is often wise to take the basal metabolic rate on an evident N. C. A. in order to convince the patient that hyperthyroidism is not present.

N. C. A. as seen today is treatable and the prognosis, on the whole, is good. The great majority of patients get well quickly, often with no more therapy than reassurance. A small proportion, possibly 10 per cent, tend to be prolonged with a tendency to recurrence. A few remain fixed for years, perhaps for life. But even the most prolonged and intractable cases sometimes suddenly get well. We cannot handle them all alike, though some need following indefinitely, many are cured at once with reassurance and should not be encouraged to remain under surveillance, which, in itself, may be poor therapy.

The general principles of treatment are reassurance, repeated as often as needed and as convincingly as possible, and a régime of diet, rest, exercise and work suited to the individual. Drugs, in general, are not indicated; digitalis and the other specifically cardiac drugs do no good. Occasionally, in selected cases, sedatives may be used temporarily to combat excessive nervousness or sleeplessness. But, in our opinion, the use of sedatives ought usually to be considered as an evasion. Explanation and reassurance rather than narcotics are

in order. Any reasonably correctable defects, such as infected teeth, should be corrected.

They should have time for sleep and time for rest and relaxation during the day. But they should not be put to bed. Sometimes a long overdue vacation is helpful, but, in general, it is possible and desirable to get the patient well *while* at work, regulating the daily régime so that the patient does not *overwork* and does stubbornly follow the rules of bodily and mental health in spite of doubt and discomforts. Diet should be adjusted to maintain the patient's weight within proper limits. Vague digestive disturbances, mentioned above, frequently require a nonirritating diet. Habits of cribbing, and poor bowel management often need correcting. On the whole, elaborate schedules of graded exercises such as were developed for the war cases has proved neither necessary nor especially helpful in civil practice. It is exceedingly difficult to apply such schedules thoroughly to patients who cannot be observed and controlled like soldiers. Treatment of N. C. A. by the more elaborate forms of psychiatry, such as we mentioned in discussion of Case VI, especially psychoanalysis, has been little tried as yet, but keeps suggesting itself as a logical possibility. Because of expense and time, psychoanalysis cannot be widely used by a cardiologist or an internist. And we should remember that we know that it is not necessary to resort to such heroic methods for satisfactory results in the great majority of cases. It is possible that in the future, the rare intractable cases will be recognized and come promptly under the case of a psychiatrist, while the cardiologist, becoming more versed in the technic of psychiatry, may be able to handle the usual cases in a more comprehending fashion. One hopes that more enlightenment from modern psychiatry will enrich what we now cherish as hard won common sense in the treatment of these common neurotics and not lead us to costly errors, as have other theories that explained the neuroses on the basis of some organic disease.

N. C. A. Complicating Organic Heart Disease.—Finally, we should like to cite two cases with N. C. A. and with organic heart disease. It must be remembered that patients with organic heart disease or, indeed, any disease, may in addition have N. C. A. These N. C. A. symptoms may be the real cause

of a disability, and may be totally unrelated to the organic disease. We were surprised recently to find that 20 per cent of a large series of young women with mitral stenosis seen in private practice complained of heart pain which was exactly like the pain described by patients with sound hearts who had N. C. A.

Case VIII.—The patient is a young woman, aged twenty-three, who was three months married and three months pregnant. She had no knowledge of any cardiac defects. She led a normal life with much exercise. She stayed up all one night at a dance, drank a little. Then during sexual intercourse became breathless, orthopneic, and raised pink-stained sputum. Orthopnea and breathlessness with signs of congestive heart failure continued for several hours and cleared. Seen the following day, her physical examination was negative except for mitral stenosis. Since then the patient has led a symptomless life with careful restrictions for twelve years, and has had 3 successful pregnancies. Following the death of 1 child by accident, she developed *severe* pain for the first time in the left chest in front, particularly below the heart and in the axilla. She became conscious of her heart beat, which was rapid. She frequently felt a desire to take a deep breath. She had anxiety dreams.

The physical examination showed no evidence of congestive failure and no change in her heart condition. Reassurance and explanation diminished at once the severity of her symptoms without change in her régime.

Case IX.—This patient, a woman of forty-two, who had rheumatic fever in her youth, but following this led to a normal life, was married and had 2 children. Following the birth of the second child, "she did not regain her strength," but suffered from breathlessness at her accustomed tasks and complained of a great sense of fatigue and of sleeplessness and precordial pain. She was seen in consultation at this time (twenty years ago) by an able cardiologist, now retired, who found mitral stenosis and apparently interpreted this as the cause of her complaints and stressed merely the necessity of a cautious régime on her and her husband. For twenty years the patient was up only a few hours a day, rarely went out, and was almost constantly conscious of her heart. Distressing precordial pain was the most prominent of her many symptoms. She never developed congestive failure. Suddenly, after twenty years of cardiac neurosis and no heart failure, without warning, she developed a right hemiplegia, probably from an embolus broken off from a thrombus formed behind the stenosed valve. She recovered partially from the paralysis, but her personality clearly changed. She became cheerful, fearless, free from complaints. There was no more mention of consciousness of the heart and heart pain. She struggled about the house doing more work than she had done at any time for the past twenty years, and remained up all day. This state continued until the patient was lost sight of several years later.

Discussion.—Case VIII explains itself.

Case IX shows the results of a misinterpretation of symptoms. If the cardiologist who first saw her had appreciated that her complaints were not due to her mitral stenosis, but

to cardiac neurosis and given proper treatment, she probably would have been improved or cured of the N. C. A. The abrupt cessation of her N. C. A. symptoms following the embolus offers a chance for speculation to those addicted to speculation on these matters. Did the embolus by causing organic change in her brain cells change her personality? Or did the obvious physical handicap of her partial paralysis provide her with a better excuse for invalidism (or outlet for her maladaptation if we prefer) than did her less obvious neurotic symptoms; and did these N. C. A. symptoms disappear because she no longer needed them? At any rate, we are satisfied for the purpose of this paper that for twenty years the patient, though possessing mitral stenosis, really was disabled by poorly treated N. C. A. and that, following the onset of an additional and organic disability, she lost her N. C. A., did more, and was happier. Such sudden changes in personality in prolonged N. C. A. appear to occur at times without any recognizable cause, psychic or structural.

Summary.—Several cases complaining chiefly of pain in the region of the heart have been presented and discussed. The facts have been stressed that pain or distress in the region of the heart that has no association with angina pectoris or coronary occlusion, is common. It is rarely organic. It is usually neurotic. It may be disabling. It is successfully treatable in the vast majority of cases. We have discussed the general management of such cases.

CLINIC OF DR. I. CHANDLER WALKER

PETER BENT BRIGHAM HOSPITAL

THE CURABILITY OF POLLEN HAY FEVER

PRESEASONAL treatment for pollen hay fever offers a cure, provided that the proper pollen extract is used; careful tests are made and judgment is employed in the manner of treatment. Two very important facts that are essential to successful pollen treatment are: that the patient must be accurate in his statement as to when and how long he has hay fever symptoms, and that the physician must know what plants are shedding pollen at that particular time in that patient's environment. A third important fact is to test the patient very carefully and accurately with those pollens which are prevalent during the patient's hay fever season. Another essential is a proper procedure of treatment and, finally, extraneous conditions must be taken into consideration for each patient. These important considerations will be discussed in detail.

Hay Fever Seasons.—The time of year or season when the patient has pollen hay fever falls into one or more of three periods, namely: spring, early summer, and late summer or fall. Naturally, the time of year that these seasons occur varies for different parts of the United States and more especially for foreign countries. For example, in New England the early summer season, during which the grasses pollinate, extends from the middle of May to the middle of July. Farther north this season is delayed two weeks, and as one goes south this season gradually advances. In Florida, a grass is in pollination in January; in Texas, cedar trees pollinate in January; in Venezuela, grasses pollinate in January. Rainy seasons in some parts of this country and foreign countries as well as cold winters in this country and Europe naturally permit of a resting period for pollination.

During the spring hay fever season, which in most parts of this country extends through March, April and May, the trees pollinate in a series. Since each tree completes its pollination in from one day (the pine) to several days (the oak) a patient must be sensitive to the pollen of more than one tree in order to experience much pollen hay fever at this season.

During the early summer season, May, June and July, the various grasses pollinate and they may cause hay fever for a period of six to eight weeks. The grass pollens are the cause of hay fever in from one quarter to one third of all cases of hay fever and the symptoms are severe. It is noted that in May some of the late pollinating trees and some of the early pollinating grasses coincide, therefore, these two seasons overlap. After the grasses have finished pollination there is in most localities a brief respite from pollen hay fever; it is a period of two or three weeks before the late hay fever season starts.

In the late summer, August, September and early October, the compositae, more especially the ragweeds pollinate. These are a profuse pollinator, cause severe hay fever symptoms for six or eight weeks and are responsible for about two thirds of all the hay fever cases.

Occasionally patients are sensitive to pollens that occur in all three seasons; more often to those pollens that occur in both early and late summer, or early summer alone, and most frequently to the pollens of late summer only. Certain grasses, for example; Bermuda grass, which pollinates after it has been cut two or three times a year, may be in pollination during the late hay fever season. Corn, which belongs to the grass family, pollinates, depending upon when it is planted, from late May to the middle of August. Although the pollen of corn does not contaminate the air which one may breathe, it does fall upon the silk and husks of the ear. Therefore, a patient who is sensitive to the grass family may have attacks of hay fever from husking corn during August and September, when the compositae are in pollination, and without tests ragweed pollen would be blamed for the cause.

All plants as regards pollens, are divided into two classes, namely: those whose pollens are borne by insects and those that are borne by the wind. A more practical division is,

those that are fragrant and pleasing to the eye and those that have little or no fragrance and little or no beauty. Those plants which have fragrance and beauty are cultivated and are insect pollinated, rarely cause hay fever. The pollen is heavy or sticky and is not dislodged by wind or air currents while in their normal condition. When such blossoms are cut from the plants and kept in a vase for a few days they may dry and considerable amounts of pollen may be blown about by drafts. However, such instances cause symptoms of only a few days' duration. Wind-borne pollens naturally lodge everywhere, even on blooms of non-hay fever causing plants so that the act of smelling of a rose in early summer may cause the inhalation of grass pollen, or in the fall, of ragweed pollen. Consequently, the patient's statement as to the cause of his hay fever may be very misleading. Roses are rarely the actual cause of hay fever and the same is true of golden rod, both of which are often suspected. The pollen of golden rod and daisy is sticky and does not blow about and consequently these do not cause hay fever in their natural habitat. The same is equally true of asters, golden glow, zinnias and fruit trees, etc.

The wind-borne hay fever-producing pollens are from plants that have inconspicuous blooms with no fragrance nor beauty, no qualities to attract insects and they produce nothing that insects desire. Examples of this type are non-fruit bearing trees, the grasses, ragweeds, tumble weeds, etc.

Geographical Distribution of Pollens.—A complete geographical distribution of hay fever pollens is out of the question in this paper. However, a brief survey may be of interest and helpful.

In the East Coast States.—As far south as North Carolina the spring season of hay fever, during March, April and May, concerns the willow, maple, oak, birch and poplar trees. The early summer season, from the middle of May to the middle of July, concerns only the grass family. June grass pollinates usually from the middle of May to the middle of June. Very few patients, however, are sufficiently bothered by this grass to warrant treatment. All of the other grasses ripen at about the same time, and since timothy is one of these and has an abundant pollen, treatment with timothy pollen seems to protect sufficiently against the other grass pollens. In the fall

hay fever season only ragweed needs to be considered; the dwarf or small variety north of Connecticut and both the small and giant south of Connecticut.

The Central States.—In Kentucky, Ohio, Indiana, Illinois and Wisconsin, blue grass, timothy grass and lambs quarters are important from May to September and the ragweeds and careless weed from July to August. In Chicago, blue grass and orchard grass cause most of the hay fever during the early summer and the ragweeds and lambs quarters in the fall. The spring season is of little importance.

The Mississippi Valley States.—All have similar seasons and similar pollens as stated above with the addition of Bermuda grass and Johnson grass. Throughout the States of Minnesota, Iowa, Mississippi, North Dakota, South Dakota, Nebraska and Kansas, blue grass, timothy grass, lambs quarters, ragweed, careless weed and sage brush are the most important causes of hay fever.

Southern District.—In Oklahoma the maples pollinate the latter part of February, the cottonwood tree in April, and both cause some hay fever. Bermuda grass pollinates from the middle of May until frost and is a contributing cause in one third of all hay fever cases. Water hemp is a very heavy pollen producer and is a very common cause of hay fever in Oklahoma and in the eastern and southern parts of Texas, Nebraska and the southern part of South Dakota, Iowa and Michigan. From the middle of August until the first of October the ragweeds are important causes of hay fever.

In Arizona and the southwest, the season of pollination begins the last of January and continues through November. Furthermore, after the annual rainfall there may be a different flora or different causative pollens from one year to the next. Rabbit bush and shad scale cause spring hay fever; Bermuda grass and June grass cause hay fever in the spring, summer and fall. The Amaranths, rather than the ragweeds, cause the fall hay fever. Outside of the irrigated districts the pollen seasons depend upon the annual rainfall. In the irrigated valleys there is a continuous hay fever season for nine months. Cottonwood pollen causes hay fever in February, the ash trees in March, Bermuda grass begins to pollinate early in April and continues for nine months. In the latter half of the

season the pigweeds and Amaranths cause hay fever and, as already stated, Bermuda grass is still in pollination. In southwestern Texas the cedar tree causes hay fever during December, January and February; Bermuda grass during April, May and June and again from the latter part of August to November. In northern Texas the grasses and ragweed pollen cause most of the hay fever.

The Mountain States.—In Colorado the cottonwood trees cause hay fever in May; blue grass and grama grass in May, June and July, and lambs quarters and the ragweeds from June to frost. In the region about Colorado Springs cottonwood trees cause early hay fever and Russian thistle, sage brush and ragweed the remainder of the summer. In Nevada, during April and May, ash, olive and black walnut trees cause hay fever from April to October. Johnson grass and Bermuda grass cause much hay fever and in addition, during July and August, rye grass. From July to October Russian thistle is most important and careless weed and red root are less important as causes of hay fever in the late summer. In Montana there is little spring hay fever from the trees; more hay fever in May and June from the grasses and 60 per cent of all cases have hay fever from July to frost and this is caused by Russian thistle, sage brush and poverty weeds.

Oregon is divided by the Cascade Mountains into two distinct areas as regards pollens. To the east of these mountains June grass pollinates in May and June, bunch grass, wheat and tall rye grass during June and July and in the late summer and fall Russian thistle pollinates from June to September. Sage brush pollinates from June to August and Atriplex from June to September. West of the Cascade Mountains are several river valleys and the pollen flora is varied. However, since 96 per cent of all hay fever patients in Oregon have the early or midsummer type of hay fever, which is caused by the grasses, enumeration of the various floras is of no interest. In Utah, during the spring season from April to June, a few patients have hay fever from shad scale. The summer season from mid-July to September is the most important in that 83 per cent of the patients have hay fever at this time. The principal cause of hay fever at this time is Russian thistle. In California the pollen flora is so varied in different districts

that it is not possible to give a detailed report. Black walnut, orchard grass, rye grass, June grass, Bermuda grass, red root, pigweed and mug wort are hay fever-causing plants which are common throughout the state. In the Sacramento and San Joaquin Valleys olive trees and Johnson grass are important. In the region about Los Angeles and Pasadena careless weed is important. About San Francisco Bay sage brush is important. In Southern California during January and February the pollens of black walnut, English walnut, live oak, scrub oak, cottonwood and cypress are prevalent. During March, April, May and June the various grasses pollinate and of these the most important are Bermuda grass, orchard grass, red top and fescue. Bermuda and ray grass pollinate practically throughout the year. During July, August, September, October and November, first the wild rye species, Johnson grass and the *Atriplexes*, then follows the western ragweed and cockle bur, and finally the *Artemisia* family.

Foreign Countries.—There seems to be no late summer or fall hay fever outside of North America and the chief cause of hay fever, namely, ragweed, is not known. In Argentina there is a tree season in early spring and a summer season due to the grasses, which pollinate during January and February. In England, France and Germany the chief causes of hay fever are the grasses and the season is similar to that in New England. In Spain there are two grass seasons; early spring and late summer, and two thirds of all cases are caused by the grass family. The olive tree also causes considerable hay fever in Spain.

Collection of Pollen.—Pick the flowers when they are just ready to shed the pollen, spread them upon sheets of smooth paper in a closed room and allow them to dry. Much pollen will be found free upon the paper. The dried anthers with the pollen inside or sticking to them can be separated from the pollen by grinding them slightly with a mortar and pestle in small amounts of carbon tetrachloride. The carbon tetrachloride with the suspended pollen is strained through cheesecloth to remove the gross fragments, and then it is allowed to fall upon smooth filter paper, while the carbon tetrachloride runs through into the flask. The same sheet of filter paper is used several times until a large amount of

THE CURABILITY OF POLLEN HAY FEVER

pollen has collected. The filter paper is then allowed to dry and the pollen forms a cake. This dry pollen is scraped with care from the filter paper and put into a clean, tightly corked bottle, where it will keep indefinitely. Pollen collected in this way is quite free from dust, is uncontaminated by other pollens, and seems to be more or less sterilized by passage through carbon tetrachloride. Pollen can be purchased from reliable firms that deal in biological products but they must be of the species indigenous to the patient's environment.

Preparation of Pollen Extract.—There are many different ways of preparing pollen extracts for use in the diagnosis and treatment of hay fever, and all of them seem to give satisfactory results when used by the worker who devises the method.

A method in general use is that of Clock, which is to extract the pure pollen grains in 66.6 per cent glycerol and 33.3 per cent saturated sodium chloride solution. Another method is that of Coca's; the dry pollens are treated with ether so that all the fats are removed, then the pollen is extracted with the following solution: sodium chloride 0.5 per cent, sodium borate in such concentration that 10 cc. of the final fluid contains about 3 cc. of tenth normal alcolide and carbolic acid in a final concentration of 0.4 per cent. Alles and Allen extract the dry pollen grains with occasional shaking in a fluid containing glycerol, sodium dihydrogen phosphate and sodium hydrogen phosphate. This extract is isotonic with blood, has a hydrogen ion concentration within the limits of normal blood sera, seems to contain all of the salt and soluble active substances present in pollen grains, and is stable.

The method used by the writer is to extract 1 Gm. of pollen in 88 cc. of normal saline with frequent shaking for twenty-four hours, then 12 cc. of absolute alcohol is added to make a 12 per cent alcoholic saline solution and the extraction is carried on with occasional shaking for another twenty-four hours. To the extracting fluid carbolic acid is added to make a final 0.4 per cent. This alcoholic, sodium chloride, carbolic acid solution is used for further dilutions of the pollen extract.

Methods of Testing for Pollen Sensitivity.

Cutaneous Test.—A number of small cuts, not scratches, each about $\frac{1}{8}$ inch long, are made on the flexor surface of the forearm. The cuts are made with a sharp scalpel, with an even pressure, so that they are deep enough to penetrate the skin without drawing blood: Sometimes in testing infants or small children the tests are made on the back. On each cut is placed a very small amount of the dry pollen to be tested. When all of the pollens have been applied to the cuts, a drop of tenth normal sodium hydroxide (4 Gm. NaOH to 100 cc. of distilled water) is added to dissolve and to admit of its rapid absorption. Great care should be used not to carry pollen from one cut to the next and not to contaminate the fluid. At the end of half an hour the pollens are washed off and the reactions read. A positive reaction consists of a white area or urticarial wheal, often irregular in shape and with outrunners or pseudopodia, surrounded very often by a flushed or rosy area.

The Intradermal Test.—This consists of the injection into the skin of minute amounts of pollen extract, usually 0.01 cc. It consists, essentially, of a parenteral injection into the body of a foreign protein. The technic is rather difficult, since the volumes to be injected must be exactly the same in the control as in the diagnostic tests, for accurate comparison of the size of the reactions. The intradermal test is so very sensitive that false reactions or pseudoreactions are a common occurrence. The tendency to multiple or group reaction to botanically related pollens, is common so that the intradermal method is sometimes unsatisfactory as an indication of the specific pollen which causes the hay fever symptoms. The most serious objection to the use of the intradermal test is the occurrence of severe local or constitutional reactions.

All plants belong to some biological family of which there are numerous members. Consequently, some plants are so closely related to each other that all members of that family will give a positive test whether cutaneous or intradermal, even though only one member may be the cause of hay fever. To illustrate this: a patient, who has hay fever in the fall of the year that is caused by ragweed pollen, will react more or less positively to daisy pollen, which is present in the air in midsummer, and which, because it is so heavy, it does not blow

about, does not cause hay fever. A patient who is sensitive to the grass family will react to the pollen of all grasses and to corn, which belongs to the grass family. Such a patient, however, would be tested for and treated by timothy pollen in the east, and Johnson grass and Bermuda grass in the south and west, and there is no necessity for treatment with corn pollen, which does not blow about to any extent. Therefore, it is necessary to test and treat the patient with only that particular pollen to which he is exposed.

Before treatment is instituted it is essential that the patient be tested with various strengths or dilutions of the particular pollen protein to which he may be exposed. The original pollen extract may be diluted so that when tests are done with various strengths or dilutions the degree of sensitivity of the patient may be established. When this is done it is usually found that the pollen which is the cause of hay fever gives a positive test in the greatest dilution or with the least amount; whereas other members of the pollen family, to which the patient is not exposed, require larger amounts of the pollen to give a positive test, and some members of the family may react very little with very large amounts.

Preseasonal Treatment.—Unless the patient is tested with graded amounts of the pollen protein, such as various strengths or dilutions it is not possible to know the initial dose for treatment or when to start treatment. Without these graded tests the first dose of treatment may be too large, thereby causing a distressing reaction, or the first few doses may be unnecessarily too weak to be of value. Furthermore, knowledge of the positiveness of the patient to various strength or dilutions of the pollen protein is an important guide in treatment. For example: a patient reacts as follows: 1: 100 is 4+, 1: 500 is 3+, 1: 1000 is 2+, 1: 5000 is 1+, 1: 10,000 is \pm , 1: 20,000 is doubtful, 1: 40,000 is 0. It is safe to begin treatment with 3 minims or 0.2 cc. of 1: 40,000. If no reaction occurs from this dose and none would be expected, the next dose would be 3 minims or 0.2 cc. of 1: 20,000, and no reaction would be expected. The third dose would be 3 minims or 0.2 cc. of 1: 10,000 and although no reaction would be expected it is known from the tests that from now on treatment should be slower and not increased so rapidly; therefore, the

fourth dose would be 5 minims or 0.3 cc. of 1: 10,000. The fifth dose would be 3 minims or 0.2 cc. of the 1: 5000 dilution; the sixth dose would be 5 minims or 0.3 cc. of 1: 5000. Since there is a greater jump from the 1: 5000 to the next dilutions of 1: 1000 than there was in the preceding dilutions, it is necessary to give two more doses of the 1: 5000, namely, 7 minims or 0.4 cc. and 9 minims or 0.6 cc. Although a mild reaction may follow the latter doses, a distressing reaction would not be expected. However, should one of these doses cause a large, red, hot, local reaction at the site of treatment or any constitutional reaction, the dose that was responsible should be repeated before proceeding with the schedule. Since the next dilution, namely, 1: 1000, caused quite a reaction in the tests, we are forewarned to proceed cautiously. Therefore, with this 1: 1000 dilution, in order to be as safe as possible, three doses are given, namely, 3, 4, and 5 minims or their equivalent in the metric system. With no reaction following these three doses, and none would be expected, it is then proper to give the 1: 500 dilution in doses of 3-4-5-6-7 minims or their equivalent in the metric system. This schedule calls for 16 treatments without any repetition. In 9 cases out of 10 an excellent result would be expected.

The above schedule is often varied to fit the degree of sensitivity of the individual patient, with consideration of the ability of the patient to tolerate an increase in the amount of pollen injected, as judged by the effect of each preceding treatment. Very sensitive patients, who require treatment with the 1:160,000 or even higher dilutions, are frequently unable to take the larger amounts of pollen extract dilutions before the time of onset of the symptoms, but they receive a great deal of benefit from treatment with the dilutions which they are able to tolerate. Less sensitive patients are sometimes treated with a 1: 100 dilution of the pollen extract in amounts of 0.1 cc. or 2 minims, 0.2 cc. or 3 minims, and 0.3 cc. or 5 minims. Since the best results are obtained when treatment is given at weekly intervals, and since 16 treatments are outlined, it is best to begin treatment sixteen weeks before the usual onset of hay fever symptoms. Treatment given at five-day intervals offers nearly as good results. Treatment that is given at more frequent intervals does not produce as satisfactory results.

Successful preseasonal treatment depends upon the following: (1) to start the course of treatment early enough to complete the schedule a week or ten days before the usual time of onset of the symptoms; (2) to test by the cutaneous method with the actual pollen extract dilutions which are to be injected in treatment; (3) to adjust the initial amount to the degree of sensitivity of the patient, *i. e.*, start with the dilution which gives no reaction, but is next higher to a dilution to which the patient gives a slight reaction; (4) to increase the amount or strength of the injections as rapidly as the patient can tolerate them with no more reaction than a slight and transient local irritation about the site of the injection (swelling less than the size of a fifty-cent piece, with surrounding flush, of less than twenty-four hours' duration); (5) to repeat any amount that causes any marked local or any systemic reaction; (6) to inject the material subcutaneously, not intradermally, intramuscularly, or intravenously.

Coseasonal Treatment.—This method of treatment differs from the preseasonal method only in that treatment is started just prior to or after the onset of hay fever. The results are not nearly as satisfactory as those obtained from the preseasonal method. Furthermore, it is hazardous because the patient is being exposed to pollen in the atmosphere at the time he receives treatment, and there is no way of estimating how much pollen the mucous membranes are absorbing at the time of treatment. In those cases where the patient is sensitive to several different species of pollens it is of some advantage to treat with some pollens coseasonally, provided the preseasonal treatment can be given with only a part of the pollens. If the patient applies for treatment after his hay fever has started and the season is a long one, it is well to give the coseasonal treatment a try; if it benefits, the patient is the gainer; if it fails, it can be stopped.

Preseasonal Combined with Coseasonal Treatment.—When a patient applies for treatment four to ten weeks before the usual onset of symptoms, a combination of the pre-seasonal and coseasonal treatment may be given. The treatment is carried out as outlined for preseasonal treatment up to the time the patient begins to have hay fever symptoms. From then on the increase in dosage is adjusted in accordance with

the condition and reactions of the patient. During the season the patient may not tolerate increased amounts of the pollen extract but may obtain much relief from repeated doses of a quantity that he can tolerate.

The results from the combination of preseasonal and coseasonal treatment are not as good as from the preseasonal treatment alone, but are much better than from the coseasonal treatment alone.

Perennial Treatment.—This method really consists of giving more or less preseasonal treatment, then continuing during the hay fever season with as much treatment as the patient will tolerate and after the hay fever season is finished and the time has arrived to again start the preseasonal treatment.

The aim of this method is, after a certain amount of immunity has been established, to hold or preserve as much of this immunity as possible until another course of preseasonal treatment can be started for the purpose of a further increase of immunity, etc. The advantage of this treatment over pre-seasonal treatment alone is that between courses of the latter there is a more or less decrease in immunity during the interval of no treatment. From the patients' point of view the inconvenience and expense of such a prolonged series of treatments may offset any advantages this method may have over the pre-seasonal method.

Seasonal Results of Pollen Treatment.—With the careful adjustment of treatment to each patient, as has been detailed by making tests with the same pollen dilutions that are to be injected in treatment and by using the proper pollens, preseasonal treatment offers much benefit to 85 per cent of cases. In districts where the pollen flora is not extensive, such as in New England, 98 per cent of patients are greatly benefited. Over a period of fifteen years the writer finds that the average results from his treatment is that 15 per cent of patients have no hay fever; 30 per cent have practically no hay fever; 40 per cent are at least 75 per cent improved; 10 per cent are 50 per cent improved, and the remaining 5 per cent are not benefited. In other districts where the pollen flora is more extensive, such as in Arizona, where Bermuda grass and June grass cause hay fever during the spring, sum-

mer and fall and in addition the amaranths cause fall hay fever, the results would not be quite as satisfactory because of the necessity of using several pollens in the treatment at the same time and because the grass season is so long.

From coseasonal treatment alone the results are not very good, but the combination of preseasonal and coseasonal treatment offers results that approximate those from preseasonal treatment. Perennial treatment gives equally good results.

Cutaneous tests with pollen dilutions at the end of a course of treatment are much less positive than at the beginning of treatment. But this greatly decreased sensitivity does not hold over completely until the next course of treatment is instituted. However, at the beginning of a second course of treatment, the cutaneous tests are as a rule much diminished over those which prevailed at the beginning of the preceding course of treatment. Therefore, with each course of treatment there is a gradual diminishing in the cutaneous tests and there is a gradual improvement in the symptomatic results of succeeding treatments.

Permanent Results from Preseasonal Pollen Treatment.—In my own experience with my own pollen extracts permanent relief has been obtained in one third of those so treated. Only a few patients have been permanently cured following one or two seasons of treatment and the majority of cures followed three, four, five and six successive preseasonal courses of treatment. If the number of those who were treated from three to six successful seasons were considered, the percentage of cures would be nearly 50 per cent. In fact, 55 per cent of all those treated four successive seasons, and 65 per cent of those treated five successive seasons have had permanent relief. About 5 per cent of the whole number have had treatment for seven or eight seasons and although they obtained complete relief from each season's treatment, their cutaneous reactions have not shown any permanent decrease and the few who have omitted a season's treatment at various times had considerable hay fever that season. Therefore, it would seem that this 5 per cent of the total would probably never be permanently cured. There are two guides or indices that tell when an apparent cure is reached and treatment may be safely omitted. One is, when the cutaneous reaction to the

causative pollen has become negative and the other is, that the pollen reaction must show a considerable decrease if not negative, and the patient should have had two seasons of complete relief from hay fever while under treatment.

About 20 per cent of those who have had permanent relief from pollen hay fever were never completely free from symptoms while under treatment. They were patients who had more or less symptoms throughout the year from causes and conditions other than pollens. This establishes the fact that pollen hay fever patients may have symptoms from causes other than pollen, that the pollen cause may be cured but there still may be more or less symptoms which must be explained on some other basis.

The positiveness of pollen tests in these cases usually diminishes with each succeeding course of treatment until the tests become negative or there is a very great reduction in the sensitivity. When this occurs it is logical and usually safe to stop treatment. Causes and conditions which produce symptoms, even though the pollen cause has been cured, will be discussed in succeeding paragraphs.

Complications in the Treatment of Pollen Hay Fever.

—In the complicated cases of pollen hay fever treatment is not as simple as in the pure pollen cases and it is this group of patients that perplexes the practitioner and the handling of these cases is best accomplished by the experienced or specialist. These complications may be perennial or seasonal.

Perennial Complications.—A mild vasomotorhinitis, a sensitive mucous membrane of the nose that is manifested only by sneezing and watery discharge, and the susceptibility to so-called "frequent" head colds, any of which conditions may be due to sensitization to some protein other than pollen, and more often due to a mild bacterial infection, may be present in a patient who has pollen hay fever. The patient may have become quite accustomed to the perennial condition and may seek relief only from the seasonal hay fever; therefore, a careful history is important. Occasionally a patient is slightly sensitive to some food protein or to an animal protein, not enough to cause symptoms throughout the year but during their hay fever season the combination of these with the pollen to which they are sensitive is sufficient to cause mild symp-

toms in treated cases. Similarly face powder, which is used more extensively in the warm months, may cause symptoms. Mechanical irritants such as soap, powders, dust, train smoke, gases, perfumes, etc., may cause little trouble throughout the year, but more trouble when the mucous membranes are already somewhat irritated by pollen. Abnormal conditions of the mucous membrane may permit aggravated symptoms when these membranes are irritated by pollen.

Seasonal Complications.—Since the cereals belong to the grass family, a patient who is sensitive to both the grass and late fall pollens, may have some hay fever in the fall from husking green corn; the corn pollen is present in the husks. Insect-pollinated flowers, when kept in the house as a bouquet, dry out, and their pollen may then blow about or be inhaled. If these plants belong to the same family as the ones to which the patient is sensitive, they may cause some irritation. Some patients are sensitive to certain foods which are eaten only during the summer and these may cause hay fever or in a treated case they cause brief attacks of sneezing and lacrimation following their ingestion. Ingestion of beers, wines, and hard liquors often is immediately followed by an attack of hay fever of a few hours' duration in a pollen-sensitized individual.

It is often difficult to differentiate between a summer head cold and an attack of hay fever, whether the patient is or is not sensitive to a pollen. Sudden changes in temperature provoke nasal secretion and fits of sneezing in many individuals, and those reactions may resemble the symptoms of pollen hay fever. In the spring and in the autumn, when the days are warm and the nights are cool and damp, many individuals, whether sensitive to pollens or not, will have an attack of sneezing and watery nose on arising in the morning and again in the evening until more clothing is put on. For the conditions mentioned in the paragraph, a vaccine often greatly benefits or relieves.

It is not uncommon to test patients who complain of hay fever at a time which corresponds more or less accurately to some pollen season, and find them negative to all proteins, including pollen proteins. A careful history, however, will often solve the problem. Usually such patients do not have con-

tinuous symptoms, but instead, a day or two of symptoms may alternate with a day or two of freedom. Their symptoms are frequently worse on cold, damp, rainy days when, of course, there is no pollen in the air, and they are much better or completely relieved on warm, sunny days, when there is abundant pollen. These are usually of bacterial cause and vaccines are indicated. Without tests and a careful history, the physician would suspect, and often would treat the patient with the pollens that were prevalent at that season with no benefit.

The odors of fragrant flowers, face powder perfumes, soap or any pungent odor, the inhalation of gases, dust, train smoke, burning leaves or cloth, etc., often irritate a mucous membrane that is already irritated by pollen and have no effect at any other season.

Conclusion.—It is evident that a careful history should be taken from all hay fever cases with especial attention to the time of year that they are effected and to other influences or complications. It is essential to know to what wind-blown pollens the patient is exposed; tests will tell to what pollens the patient is sensitive, but the physician must know to which the patient will be exposed. Before treatment is given tests should be made with different strengths or dilutions of the causative pollens. Such tests will help to select the proper pollen since it will react strongest, they will tell when to start treatment since the number of treatments will be defined by these tests and the tests are a guide to the different doses to be given. Treatment should be intensive with as few pollens as possible. It is not advisable to treat with a mixture of pollens from very closely related plants that pollinate at the same time because intensive treatment with one of them will protect against exposure to the group. Definite directions and a well advised schedule of treatments may have to be altered in any particular case; the schedule may call for too strong a dosage in one case or too weak in another. Such directions and schedules are a guide to proper treatment and if they are determined by previous tests they are usually satisfactory. Directions and schedules that are formulated without a previous test on the patient to be treated are apt to be valueless.

CLINIC OF DR. JAMES M. FAULKNER

THE THORNDIKE MEMORIAL LABORATORY, SECOND AND
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY
HOSPITAL AND THE DEPARTMENT OF MEDICINE, HARVARD
MEDICAL SCHOOL

THE PRACTICAL MANAGEMENT OF CONGESTIVE FAILURE

CARDIAC failure of the congestive type is one of the most common problems encountered in medical practice. Although a familiar subject, it is none the less full of interest on account of the variety of its manifestations and of their response to treatment. To be sure, the main principles of treatment are well enough understood but their practical application to patients with congestive failure provides many opportunities for the display of resourcefulness on the part of the clinician. It is a condition where minor tactics often play a decisive rôle in the outcome and it is to these homely practical details that we shall chiefly devote our attention today. The discussion will be grouped around *general measures, drug therapy and mechanical measures.*

General Measures.—*Rest.*—In the treatment of severe grades of congestive failure, rest must mean a great deal more than mere confinement to bed. Its real meaning is best understood in terms of metabolism by saying that the metabolic rate should be maintained as close to the basal level as practicable. In order to achieve this, there must be a minimum of muscular activity, of mental and of digestive activity and an attendant strong enough to move the patient should be constantly available to spare him any unnecessary exertion. While acutely ill he must, of course, be fed, bathed and shaved and, during this stage, the bowels are best emptied by enema, preferably by the two-way enema or low colonic irrigation. The latter

possesses the advantage of not requiring the use of a bed pan, so that the patient does not have to be moved. The bed pan is a physical and mental hazard to the bed-ridden cardiac. For many it is less of a strain to be moved onto a commode beside the bed. The stools must be kept soft with cathartics so that there is no expulsive straining.

The optimum position of the cardiac patient in bed will depend upon the degree of orthopnea to which he is subject. A few with extreme orthopnea will be most comfortable in a chair. A new "cardiac bed" in which the foot lets down while the head comes up is a great comfort for these patients. In determining how long to keep a patient with congestive failure in bed, one has to bear in mind that the longer he remains in bed the more skeletal muscle tone he will lose and, with it, peripheral vascular tone. This will tend to increase the strain on the heart when he first gets up. For this reason and on account of the danger of hypostatic pneumonia, it is advisable to get aged patients sitting up in a chair just as soon as possible. For the same reason, gentle massage and passive exercises are worth-while procedures during convalescence.

Mental rest is also an important objective in the treatment of cardiac failure. If the condition is acute, the patient is apt to be the prey of anxious thoughts and disturbed sleep. Under these circumstances morphine is indicated as much for the comforting euphoria which it induces as for the reliability of its soporific effect. Later on, of course, the main dependence for sleep must be placed on less habit-forming drugs such as the barbiturates or chloral hydrate. Restless patients often feel better during the day if the "edge" is taken off by a mild sedative such as phenobarbital, $\frac{1}{2}$ grain three times a day.

The sick room must be as restful and quiet as possible and kept at an even temperature. Visitors should be strictly limited and should be cautioned against allowing the patient to do much talking.

Diet.—The diet of a cardiac should consist essentially of concentrated low residue, high carbohydrate foods given in small amounts at frequent intervals. This accomplishes several purposes. It avoids undue strain on the heart from overloading the stomach, it reduces the amount of bowel residue

to be expelled, it furnishes glucose in readily available form to replenish exhausted glycogen stores in the myocardium, and it minimizes the stimulation of metabolism from specific dynamic action. In the critical stages the carbohydrate may be given in the form of concentrated dextrose solution intravenously. For oral use fruit drinks sweetened with glucose or lactose are employed. The Karell diet (800 cc. of milk per day) is useful on account of its simplicity and its low caloric content. As Master has shown, the basal metabolic rate of a cardiac patient may be lowered to as much as minus 30 by a low caloric diet. Easing the load on the heart in this way may prove useful in the treatment of obstinate cases of congestive failure.

The fluid intake must, of course, be rigidly restricted. Not more than a quart a day is a good general working rule. It is well to ration it out in small amounts at stated intervals during the day so that it will not all be squandered before noon. Salt also should be limited because of its action in binding water in the tissues. In most cases a restriction of salt to what has been put into the food in the kitchen will suffice, but an obstinate few will require a completely salt-free diet. The substitution of potassium chloride for sodium chloride as a table salt is worth while in patients with chronic edema. The potassium chloride will furnish almost as much savour without the water-binding effect of sodium chloride.

Oxygen therapy is indicated if cyanosis becomes marked. The oxygen tent or chamber is the method of choice. but if not available, the nasal catheter will usually prove satisfactory. The disadvantage of the nasal catheter method is not that it does not deliver oxygen in sufficient concentration to the nasopharynx but that it is apt to be uncomfortable for the patient. The chief sources of discomfort are insufficient saturation of the oxygen with moisture so that the patient's throat is burned, and the use of catheters which are too stiff. If due attention is paid to such details the patient will often experience a feeling of marked relief when oxygen is started and may drop off to sleep. Objectively there is usually an improvement in the color and the respiratory and pulse rates are slowed. Improvement in intraventricular conduction during oxygen administration has been demonstrated and suggests that the

efficient functioning of the myocardium itself may be enhanced by this procedure.

Drug Therapy.—*Digitalis*.—A word has already been said about the important place which the opiates and the sedatives occupy in the treatment of congestive failure. Of the specific cardiac drugs, digitalis, of course, still ranks foremost. Digitalis therapy has been somewhat confused by the myriads of proprietary preparations which have appeared on the market in recent years. These preparations vary widely in potency and a few still make unwarranted claims in regard to not causing "gastric irritation" and nausea. The nausea of course is due to an effect on the vomiting center and not to any local effect in the stomach. A digitalis preparation which will not produce nausea in large doses is not a potent preparation. Occasionally one encounters a patient who has been conditioned against digitalis by having been nauseated by it in the past. To such a patient the smell and taste of digitalis is nauseating and if they are to take it by mouth it must be given in the form of a coated pill. It is very seldom that one finds a person who is really sensitive to digitalis.

In determining the dosage of digitalis to be administered to a given patient the Eggleston formula of 1.5 grains. (0.1 Gm.) of the powdered leaf or 15 minims (1 cc.) of the tincture for every 10 pounds of body weight is a useful guide. There is so much variation in individual tolerance to the drug that even if all preparations were of fixed potency, no formula for dosage could be more than a rough index. In general, the tolerance to digitalis is proportional to the total metabolism. For this reason, children, active ambulatory patients and patients with fever or hyperthyroidism require relatively larger doses—sometimes twice as much per unit of weight—as compared to the aged, the inactive bed ridden and those in whom a significant proportion of the weight is due to inert edema fluid. Since it is impossible to predict exactly how much a given case will tolerate it is well to approach the estimated total optimum dose gradually. For example, if it is desired to digitalize a 150 pound man in twenty-four hours, the estimated total dose would be $\frac{1.5 \times 0}{10} \times 1.5 = 22.5$ grains. This would be divided up as follows:

	<i>Individual dose.</i>	<i>Total dose.</i>
Initial dose.	9 grains	9 grains
Three hours.	6 "	15 "
Six hours.	3 "	18 "
Nine hours.	1½ "	19½ "
Fifteen hours.	1½ "	21 "
Twenty-one hours.	1½ "	22½ "

Inquiry as to anorexia or nausea should be made before each dose is given and the drug discontinued at the first sign of toxicity. If no effect whatsoever is noted, it may be continued in doses of 1½ grains three times a day until an effect is produced. If the patient has had an uncertain but apparently inadequate amount of digitalis, he may likewise be given 1½ grains three times a day. This dosage is also useful in digitalizing ambulatory patients who are not under close supervision, as in the average person one week of it gives approximate digitalization. In regard to digitalis dosage the dictum of Withering published in 1785 still holds good. He wrote: "Let the medicine, therefore, be given in the doses, and at the intervals mentioned above; let it be continued until it either acts on the kidneys, the stomach, the pulse, or the bowels; let it be stopped upon the first appearance of any one of these effects." Other indications for discontinuance of the drug are the appearance of yellow vision and very frequent extrasystoles or bigeminal rhythm.

The electrocardiogram may yield further information in regard to the effect of digitalis on a given patient. It may show, by a specific change in the contour of the T waves, plain indications of a drug effect long before toxic signs appear. It may also give evidences of toxic action not readily detectable by other means of examination (partial heart block, frequent extrasystoles or periods of complete heart block in auricular fibrillation). In children, however, the electrocardiogram may remain normal in the presence of digitalis poisoning.

Some of the drug houses, in order to assure the consumer of a potent product, now dispense their digitalis products in terms of cat units. The cat unit is approximately equal to 1½ grains (0.1 Gm.) of the digitalis leaf (U. S. P.) which is standardized in frog units. For convenience and precision of dosage the pill prepared from the whole leaf is very satisfactory for routine oral administration. Occasionally it is necessary to

administer the drug parenterally, the indication being more often gastric disturbances than the necessity for extreme haste in digitalization. It is here that some of the purified extracts of digitalis have a place. The most powerful of these is crystalline ouabain, which is one thousand times as potent as standard digitalis. One mm. of ouabain intravenously is the maximum dose in an adult and should be divided into at least two injections given one half an hour apart. Strophanthin is a related compound of approximately equal potency derived from another source. These powerful drugs must be used with greatest caution, particularly if there is any question as to the amount of digitalis the patient has had just previously. Satisfactory preparations are also available for intramuscular use. Rectal administration is less satisfactory because one is never sure exactly how much has been absorbed. Dosage is the same whichever way the drug is administered. The average daily maintenance dose of digitalis is $1\frac{1}{2}$ grains but some individuals cannot take half this dose and others will require three times as much.

By far the best results from digitalis are to be expected in the group of patients suffering from auricular fibrillation with rapid ventricular rate. The chief benefit in these cases is the elimination of the premature, inefficient, ventricular contractions. No such dramatic results are seen in auricular fibrillation with slow ventricular rate or in normal rhythm. The contrast is indeed striking, but should not obscure the fact that digitalis is usually of definite, although limited value, in the latter group.

Diuretics.—The importance of diuresis *per se* in the management of congestive failure can not be too strongly emphasized. Edema is much more than an inert burden of water, for in many ways it acts as a vicious aggravating factor to increase the work of the heart. In the lungs it causes respiratory distress and brings about a lowered oxygen tension in the blood with all the resulting train of altered function in vital organs, including the myocardium. In a limb it has been shown to increase the minute circulating volume of blood, again throwing an extra burden on the heart. Its presence in the liver, the kidneys, the intestinal mucosa, indeed in the myocardium itself, interferes directly with the function of

those organs. Edema, therefore, is to be regarded as a harmful complication to be eliminated as promptly and as completely as possible.

Of the specific diuretics we need discuss only the two most important groups—the mercurials and the purines. The most satisfactory mercurial on the market today is salyrgan. This drug combines a powerful diuretic effect with a minimum of toxicity. Being a mercury compound it is contraindicated in the presence of advanced kidney disease but appears to exert no deleterious effect on the normal kidney. I have had occasion to use it twice a week over a period of three years in a patient with congestive failure and a mild degree of arteriosclerotic nephritis without any aggravation of the renal condition. It possesses the advantage over the milder purine diuretics of greater reliability of action and—because it is given intravenously or intramuscularly—of not upsetting the stomach. The dose varies from $\frac{1}{2}$ cc. in children to 2 cc. in adults. Preferably it is given intravenously, but if veins are not available it may be given intramuscularly in the deltoids. If it is deposited subcutaneously or in edematous tissue where absorption is slow a slough will result. A diuresis usually appears within a few hours and persists for twelve to twenty-four hours. The dose may be repeated after three days. The drug is more effective if the patient is mildly acidotic, so that if no diuresis follows the first injection, a course of ammonium salts should precede the second. These salts possess diuretic properties themselves. Ammonium nitrate is preferable to ammonium chloride because it is less irritating to the gastrointestinal tract. It is best given in $7\frac{1}{2}$ grain (0.5 Gm.) enteric coated pills—three pills every three hours for 6 doses on the day before and on the day of the injection. With this adjuvant a hitherto ineffective mercurial will often prove active.

The purines possess distinctly less diuretic effect than the mercurials but they have the advantage that they can be taken by mouth. They are indicated in the milder cases where the mercurial has proved ineffective. Caffeine is the mildest diuretic of the purines and too weak to be of clinical importance. The most commonly employed are theobromine and theophyllin. The former is given in doses of $7\frac{1}{2}$ grains (0.5 Gm.) of the pure alkaloid or 15 grains (1 Gm.) a day for

two or three days of theobromine sodium salicylate three times a day. Theophyllin is given in the same manner in doses of 4 grains (0.25 Gm.) three times a day. Both of these drugs have the disadvantage of frequently causing gastric irritation, nausea and vomiting. The purines may be used in conjunction with the mercurials to obtain an enhanced effect. A new preparation called "mercururin," which combines the two in one ampule has proved to be a very powerful diuretic—the two drugs seeming to have an additive effect.

Mechanical Measures.—*Venesection.*—Venesection is indicated if the venous pressure is high, as evidenced by engorged neck veins, or if there is acute pulmonary edema. If there is no anemia from 400 to 600 cc. of blood should be withdrawn.

Tapping.—Abdominal paracentesis is worth while if the ascites is considerable in amount (more than three liters) and may be followed by a sustained diuresis. Thoracentesis is justified if the amount of pleural fluid is sufficient to embarrass respiration. Removal of subcutaneous fluid by means of Southey tubes is useful in obstinate cases.

Surgical Measures.—In the last few years total thyroidectomy has been advocated in the treatment of certain obstinate cases of congestive failure. The procedure is radical and technically difficult. It requires the closest sort of organized teamwork between internist, surgeon and nursing staff. The patients must be picked with care, the ones most suitable for the operation being those who are edema-free in bed but who can not get up without developing congestive failure. Under ideal conditions, a fair proportion of such cases will be improved by total thyroidectomy. It is not likely that it will be frequently resorted to.

The proper management of a case of congestive failure involves quantitative measurements of the effectiveness of the various procedures employed. The best rough index is a chart of the daily fluid intake and output. When the patient can be moved a weight chart is an invaluable check. The rapidity of weight loss in diuresis is sometimes astounding, reaching as much as 10 pounds in a day. The chart may also demonstrate the loss of edema "hidden" in the tissues which gave no physical signs of its presence.

Neurologic examination confirmed her subjective complaints (Fig. 173). There was definite atrophy of the shoulder girdle. All deep reflexes were exaggerated on the right, and the left Babinski was equivocal.

x-Rays of the spine showed a forward displacement of the fourth cervical vertebra. Lumbar puncture showed normal dynamics and the fluid was normal except that the protein was increased to 58 mg. Iodized oil injected into the cistern could be seen to pass the cervical enlargement in a thin stream.

A cervical laminectomy was performed. The entire cervical cord was found to be reduced to a thin-walled sac filled with spinal fluid which had evidently caused an atrophy of the walls of the canal by pressure and so had permitted a pathological fracture. The sac was incised along the midline posteriorly over a distance of about 3 cm. opposite the fifth vertebra. It was lined with glistening ependyma, and the cavity evidently communicated with the fourth ventricle.

The patient made a good operative recovery, and was relieved of pain. Her arms improved, and she was able to get about. In the course of a few months, the weakness of the legs recurred and progressed in spite of x-ray treatments, so that the patient was helpless when last seen a year after operation.

Case II.—A mechanic of thirty-two was admitted to the Massachusetts General Hospital on account of a "hammer" deformity of the left middle finger. A plastic operation on the tendons was contemplated, but neurological examination showed a characteristic "dissociated" sensory loss, scoliosis and facial asymmetry. The patient was slightly ataxic, and it was learned that the scoliosis and unsteadiness had been present since infancy. This was before the days of either x-ray treatment or operation for syringomyelia, and all that could be done was to amputate the last phalanx of the affected finger, which was in the patient's way.

Case III.—A man of fifty-five was admitted to the Boston City Hospital following an attack of faintness. He had lost consciousness without obvious cause four times during the previous two and a half years. He had been having pain in both arms for five years, and some tingling in the left hand for a year and a half. He had lost much weight. There was atrophy of the deltoids and of the hands, especially the left. The pain was, at times, severe enough to require morphine. There was a Horner's syndrome. All modes of sensation were impaired in the left hand, but only pain and temperature in the right. There were exaggerated reflexes, a Babinski sign, and loss of position sense in the left foot. Lumbar puncture showed a partial block and increased protein.

Cervical laminectomy revealed two fusiform enlargements of the cord, one at C₄ and the other at C₆. Both were opened; the lower one contained about 30 cc. of xanthochromic fluid, the upper was solid. The walls were dark and rough. Following operation the pain was less severe, but there were no objective changes. The patient's symptoms gradually progressed and he died fourteen months later.

Case IV.—A man of twenty-four was admitted to the Boston City Hospital complaining of weakness, stiffness and numbness of the right leg gradually increasing for three years. From seven to nineteen years of age, he had had attacks of unconsciousness with crude visual hallucinations. About a year before admission, his right arm also became weak and numb. Vision had

always been poor in the right eye. Examination showed facial asymmetry (Fig. 174), scoliosis, scars of painless burns on the fingers (Fig. 175), and

Fig. 174.—Case IV. Facies.

atrophy and fibrillation of various muscle groups of the shoulders and arms. There was bilateral clonus, Babinski's sign, and ataxia of the legs.

Fig. 175 Case IV. Painless burn of right hand, atrophy of hypothenar eminence.

There was a slight optic atrophy and a bilateral paracentral scotoma. Several lumbar punctures were performed, one of which showed 9 lymphocytes, another a protein of 83.

Several x-ray treatments were given, but the symptoms became worse rather than better. Finally, laminectomy was resorted to, and this disclosed an enormous cavity occupying the entire cervical cord, filled with spinal fluid. It was incised over a length of about 15 cm. The lining was a glistening white, and the walls nowhere more than 2 mm. in thickness. The cavity appeared to communicate with the fourth ventricle. The patient made a striking improvement after operation; not only did the sensory signs regress, but motor power was greatly improved, so that the patient could use his hands, walk long distances, and drive an automobile. The operation is now four years ago; the symptoms have very gradually returned, but have not yet reached their original severity.

Case V.—A man of twenty-eight entered the Boston City Hospital with the complaint that for three months his gait had been unsteady, especially at night. He also had a sense of coldness in the left arm and leg. Examination revealed asymmetry of the face, scoliosis, huskiness of the voice, and nystagmus in all directions. There was a loss of pain and temperature sense over the left side of the face, and also over the first four cervical and first and second sacral segments on both sides, without disturbance of sensation of touch. There was slight atrophy of left thenar muscles, and all deep reflexes were increased. The Babinski reflex was positive on both sides. Vibration and position sense was impaired in both feet, and there was an astereognosis of the left hand. Lumbar puncture showed normal dynamics and negative findings except for a protein of 58.

The patient was given x-ray treatment over the entire spine. In three months there was definite improvement, and he returned to work.

The Diagnosis.—These cases, picked almost at random, may serve to indicate the fact that syringomyelia does not by any means present the stereotyped clinical picture which most textbooks describe. To be sure, a "dissociated" sensory loss in the arms and some atrophy of the muscles of the hand is the rule. Indeed, the symptom of painless burns from cigarettes (among women, flatirons and stoves used to be equally common agents) is practically pathognomonic. But the standard teaching that injury to the long tracts is rare, should be abandoned. Some degree of spasticity, ataxia or loss of vibration sense is extremely common, and may be the presenting symptom. Pain in the arms is also often encountered. Atrophy of the muscles of the tongue or face with fibrillation has, of course, long been recognized, and so has the presence of nystagmus, but the frequency of their occurrence has been underrated. The explanation usually given is that the cavity extends into the medulla, but it seems probable that involvement of the cervical cord alone may suffice to produce it. A Horner's syndrome may occur.

Two somatic manifestations are of importance, first because they are almost constantly present, second because they may be immediately evident on inspection, and third, because of their possible significance in the interpretation of the nature and course of the pathologic changes. They are facial asymmetry and scoliosis. The facies may be strikingly similar from case to case (Figs. 175-177). Typically, the face is thin, the chin sharp, and the nose slightly out of line with the chin. One cheek is ordinarily more hollow than the other. The "bite" may be crooked. Pimples are common. Whether this facies actually is a "family resemblance" is an open question,

Figs. 176, 177.—Facies of two other patients, whose cases are not reported here. Notice "family resemblance"; rather long face, sunken cheeks, deep nasolabial fold, various slight asymmetries.

since we shall see below that the tendency to the disease is doubtless hereditary. It is perhaps more likely that both this and the scoliosis are the result of muscular imbalance, in turn dependent upon involvement of the grey matter. The fact that these manifestations may often be traced back to early childhood—as indeed the ataxia and some other symptoms may also be—is evidence that the underlying pathologic change is congenital.

Little emphasis has been placed upon *cerebral* symptoms, which have, however, been observed in so many cases that they can scarcely be dismissed as a coincidence. Syncope and

convulsions are the commonest, but others have been reported. It has seemed to me that a dependent, self-pitying attitude, sometimes combined with emotional instability and a tendency to blame others, was of frequent occurrence, but possibly this is merely a reaction to an affliction which is often progressive and crippling, and may occur in adolescence.

Visual symptoms are also encountered. Optic atrophy with enlarged blind spots is the only type I have observed personally, but papilledema has been reported. The possibility of confusion with multiple sclerosis and syphilis is obvious.

Alterations Produced in the Spinal Fluid.—The following data are summarized from the book "*The Cerebrospinal Fluid*," now in the course of preparation by Dr. H. H. Merritt, by his kind permission: in a group of fluids from 31 cases of syringomyelia, the pressure was over 200 cm. of water in 7 instances, for an unknown reason. In 2 cases, a subarachnoid block was demonstrated. In almost half the cases (including these two) the protein was higher than the normal upper limit of 46 mg. Occasionally a slight increase in cells was found. On the whole, therefore, examination of the spinal fluid is of little aid in the differential diagnosis from multiple sclerosis and cord tumor.

Etiology.—It has long been suspected, although on rather scanty evidence, that syringomyelia is the result of a hereditary defect. The disease may occur in association with other congenital defects and has been reported in two members of the same family. The observations of Ostertag,¹ that a similar condition exists as a recessive Mendelian trait in some strains of rabbits, lend a new weight to the theory. In these animals the lesions may vary from microscopic size to cysts which cause complete paralysis. In human beings also lesions of typical histology but too small to cause symptoms are a fairly common postmortem finding, usually in association with other neurologic diseases, for the spinal cord is seldom examined in subjects who have had no symptoms. It has been seen in this laboratory in association with spinal syphilis and myelomalacia, and has been reported with multiple sclerosis² and acromegaly.³

Alternative theories are that the cyst is the result of an as-

ceding neuritis or of a spontaneous hematomyelia dissecting up and down the gray matter. The fact the symptoms may be of insidious onset in childhood, and may progress irregularly or even regress, renders both improbable, as does the histology of the lesion. The cases in which an abscess of a finger has produced an ascending lymphangitis, and the signs of syringomyelia have then been discovered, may perhaps equally well be interpreted as instances of the increased danger of trauma and infection when the sensation of pain is absent from its sentry post. Hemorrhage into the gray matter may occur, and local pressure on the cord (as from a tumor) may cause necrosis chiefly in the gray matter, but in neither instance is a progressive process initiated. The symptoms of syringomyelia may often be first noticed, and possibly made worse, by injury, but close inquiry will almost always elicit evidence that the disease dates back to childhood.

Pathology.—The lesion usually described is one which begins in the gray matter of the cervical cord, and gradually spreads upward and downward. The fibers carrying the sensations of pain and temperature are usually involved more than any other group, either in the commissure or in the posterior horn. It is doubtless for this reason that the sensory loss may be greater on one side than on the other. The fibers subserving the sensations of position, vibration and (probably) touch run directly from the posterior root ganglion into the posterior column without a synapse, and are, therefore, less often injured, but they too may suffer. An irregular invasion of the anterior horns accounts for the muscular atrophy. The process is practically always most intense in the cervical region, but may spread up to the pons and down to the lumbar enlargement. The gray matter is chiefly involved, but the white matter may be injured also, perhaps in part by pressure.

It is usually stated that in true syringomyelia the cavity is distinct from the central canal and fourth ventricle, and contains a yellow fluid. If the cavity communicates with the subarachnoid spaces, the condition may be designated as hydromyelia, and it is often implied that this is a relatively benign condition. The experience gained by surgical interventions makes it appear probable that there is no real distinction between the two. In only one of my own cases has

the cavity contained xanthochromic material, rich in protein. In the six others, it contained spinal fluid, and evidently connected with the fourth ventricle. There was, however, no particular difference in the manifestations or clinical course of the disease in the two groups respectively, in my own cases, and in others in the literature. Usually the cavity is lined with a glistening white ependyma if it contains spinal fluid, and with a rough gray or brown glial growth if it is discrete. In one of my cases, both coexisted. The cysts containing spinal are usually the larger ones, and as in the first case reported above, may actually distend the cervical canal. It is no wonder that pain is produced by pressure on posterior roots. One would expect that the Queckenstedt test would more often show a block. It is probable that the fluid wave may be transmitted through the thin sac wall.

Histologically, the new formed tissue is found to be composed of fibrous astrocytes. There is usually little evidence of active proliferation; few nuclei lie in the thick feltwork of fibers. Vessels are rare. Occasional accumulations of blood pigment occur. No real inflammatory lesions are seen in the cord, but a mild meningoencephalitis over the brain has been reported. So has hydrocephalus.

The gliotic tissue may undergo a gliomatous degeneration. At least, *this is the current interpretation.* It is possible that central tumors, and perhaps other processes, may produce cavities in the gray matter which are entirely secondary and not progressive. Further study is needed to settle this point.

Treatment by x-Ray.—In every case, as soon as the diagnosis is made, roentgen radiation should be administered. It appears to be more effective early in the disease than later, and perhaps more should be expected of it as a preventive than as a curative measure. It is not universally effective. Improvement has been obtained in about 60 per cent of the cases reported in several series, but my own experience has not been as favorable. Some cases are definitely made worse by radiation. There is further the danger that excessive treatment will produce changes in the skin which may render subsequent operation difficult. It is, however, always worth trying, and may even be used as a diagnostic measure, for no other condition likely to be confused with syringomyelia is

likely to be affected favorably. Multiple sclerosis, for example, is distinctly aggravated.

Operative Treatment.—Atypical instances of syringomyelia may easily be mistaken for cord tumor, and doubtless many isolated cases have been operated upon since the early days of spinal surgery. The first surgeon bold enough to recommend opening the sac was Elsberg,⁴ as far as I have been able to learn. A few subsequent operations are recorded, but the procedure remained a novelty until Poussepp reported two successful cases before the International Congress of Neurology in Paris in 1925.⁵ Since then a large number of similar operations have been reported, the majority of them

Fig. 178.—Hands of a patient with syringomyelia (not reported here) to show contractures. *A*, Before operation; *B*, after operation.

from Russia, where the disease appears to be unusually common.⁶

In general, the reports have been favorable. Most striking, both in the literature and in my own cases, has been the decrease of analgesia and anesthesia, and “before and after” charts have been frequently used as evidence of the efficacy of the procedure. Unfortunately, it is seldom the sensory disturbances which drive the patient to seek relief. The motor weakness in the hands and the injury to long tracts are less regularly improved, but sometimes definite benefit is demonstrable (Fig. 178). It is difficult to form an estimate of the proportion of favorable results from the literature, for evi-

dently successes tend to be reported in greater numbers than failures. In the 7 cases which I have observed personally, substantial improvement was observed in 4, although in all of them there has been some progress of symptoms since operation. In two others a decrease of the band of analgesia resulted, which looked well in the patients' record, but did not materially improve their ability to help themselves. Juzelevskij, who reported the largest series on record, gives somewhat similar statistics; 16 out of 22 cases were improved.⁷

On the other hand, the operation has not proved as dangerous in my experience as it is sometimes alleged to be. There have been no deaths, and no separation of the wound edges, which has frequently been recorded. One patient suffered a slight increase in the ataxia of one hand; otherwise, the postoperative condition has been no worse when it has been no better than that before operation.

The question has often been raised—does the opening in the sac close again? Recurrence of symptoms has taken place in several instances, and in a case reported by Frazier⁸ the cyst had reformed. To avoid reaccumulation of fluid, it has been suggested that a drain of fascia or rubber be introduced into the drainage opening. From the pathological point of view, this would seem ill advised. A foreign body in contact with nervous tissue invariably becomes encapsulated in a mesodermal scar, which is exactly what one would wish to avoid. The problem is better met, it seems to me, by making the incision the entire length of the sac, or at least as long as the laminectomy allows. In the majority of instances, the edges will then gape apart and collapse into contact with the floor of the cyst. Whether adhesions will form, and whether the pia will obligingly regenerate to form a false passage from the lumen to the surface, must be left to future observation to decide. It would seem *a priori* unlikely, but some cases remain improved years after the operation. This brings up two minor technical points. The first is, where should the sac be opened? Poussepp suggests through the posterior horn of one side. My own policy has been to incise where the sac is thinnest, but usually in the midline, and this has not led to noticeable ataxia of the legs. When a long incision (of several centimeters) is made, bleeding may be troublesome, as the

posterior spinal vessels are too small to clip or tie successfully and too intimately attached to the cord to coagulate as they lie. If, however, they are gently raised on a dural hook, a light cutting current may be used to seal them without injury to nervous tissue. Collateral circulation is sufficiently rich to make up for any loss of blood supply.

Indications for Operation.—Weighing all of the considerations which have been enumerated, when should we recommend operative treatment? There is evidence that operation does not permanently halt the progress of the disease, and closure of the drainage opening is particularly to be feared if the sac is small. It is, therefore, not to be advised as a measure of prevention, which x-ray treatment appears sometimes to be. Radiation should be given a trial first, therefore, probably in all cases.

Pain is usually an indication for operation. It is seldom relieved by x-ray treatment, but usually yields to relief of tension within the sac. As pain is an important symptom of syringomyelia, the indication is an important one.

Spinal block, if it occurs, should probably prompt an operation. If there is an obstruction to the flow of fluid, the walls of the sac must inevitably be subjected to pressure, and this in turn is likely to be responsible for at least some of the symptoms. An increase in the spinal fluid protein is to be taken as presumptive evidence of block.

Finally, in many cases *economic disability* is a situation which justifies the pursuit of even remote chances of benefit. It is in this group of cases that the most marked and most gratifying improvement is obtained, and it is fair to hold such a possibility open even to extensively crippled patients.

CLINIC OF DR. STANLEY COBB

MASSACHUSETTS GENERAL HOSPITAL

CONCERNING FITS*

If a patient greets you in your office with the complaint, "I have frequent headache," your mind runs rapidly over a list of possible causes, a shorter or longer list according to the extent of your experience. Many are rapidly eliminated as impossible or improbable in this patient. Nevertheless, days of study will be spent before the list of possibilities is cut down to a workable few. But if a patient greets you with, "I have fits, doctor," often your mind is filled with a vague concept of a "disease" called "epilepsy": inherited, deteriorating and hopeless. Such a concept frequently inhibits further intelligent research into the etiology of a particular case.

It is my contention that epilepsy is a simple, fundamental manifestation of nervous disintegration. "Disintegration" means here the loss of more or less of the functional harmony of the central nervous system. Integration is the main function of the central nervous system; it is the process of building up useful behavior patterns out of the many and varied stimuli that reach the cord and brain; physiologically it works by summation, facilitation, inhibition, long circuiting and co-ordination. The essence of the process is delay of incoming stimuli to allow for association and for reaction conditioned by past experience. Now this integration may be interfered with by physical or chemical injury to nerve cells, or by conditions which alter nerve function. Because I believe that a condition of interference with integration is essential to the production of fits, and because the interfering conditions are many and diverse, I believe that epilepsy cannot be called a disease.

* Read at the meeting of the Suffolk District Medical Society, March 28, 1935, Massachusetts General Hospital.

To illustrate this I have made a chart (Fig. 179*) enumerating 60 conditions associated with convulsions in man, some rare, some common. These 60 I have tried to explain on one or another physiological basis, and for this purpose have

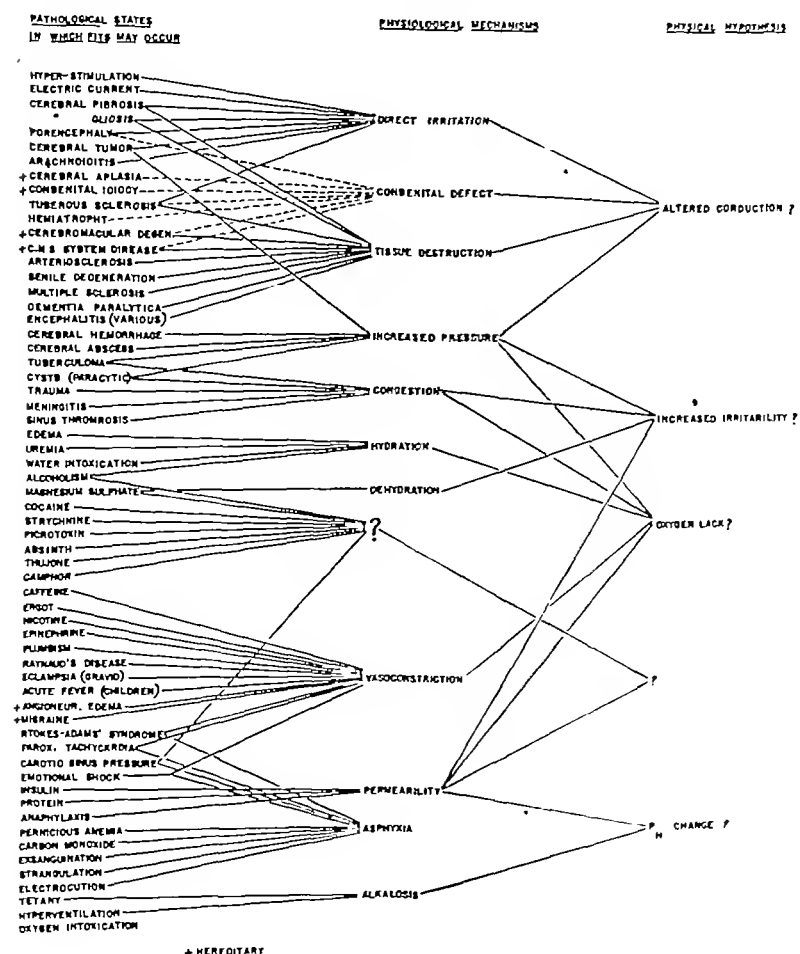

Fig. 179.

joined them by lines to 12 possible physiological mechanisms which have gone beyond normal limits and become pathological processes. These relationships are admittedly speculative.

* A similar chart was published by me four years ago in the Arch. Neurol. and Psychiat., 27: 1245, 1932. The present chart is a revised and enlarged edition.

For a few there is good evidence; for others very little. Even more speculative are the four "physical hypotheses" which make up the last column; the most reliable symbol here is probably the large question mark! But there is no use in gathering data if they are not classified, analyzed and thought about. So the speculation is justified that altered conduction of the nerve impulses, increased irritability of the nerve cells, oxygen lack of the nerve cells, or change in acid-base equilibrium are probably important factors in many convulsions.

For the first two hypotheses we have the recent work of Gibbs, Davis and Lennox^{1, 2} which shows by means of beautiful electro-encephalograms that epileptic seizures are accompanied by a change in the cerebral electrical potentials; this is recorded as a wave that has an apparently significant shape. Oxygen lack seems important because so many of the 12 physiological mechanisms may give rise to anoxemia, and because clinically, interference with circulation seems to be one of the surest methods of inducing loss of consciousness and convulsions. Acid-base balance may be important, but the evidence for it at present is based on a few observations on the blood of epileptics before attacks where there was a change toward the alkaline side, on the analogy with tetany, and on the occasional precipitation of seizures in epileptics by hyperventilation.

The inheritance of epilepsy is too much emphasized by physicians. Although the evidence supporting my opinion is far from complete, I believe that most convulsions are associated with acquired abnormality of the nervous system³ and the acquired character cannot be inherited. On the other hand an injury to the brain may precipitate, and cause to become overt, a latent hereditary tendency to convulsions. The evidence for this is the observation that among the relatives of "traumatic epileptics" the incidence of epilepsy is about six times as high as among the general population, although it is only 60 per cent of the incidence among relatives of "idiopathic epileptics."⁴

In the list (Fig. 179) trauma and birth injury (causing fibrosis, gliosis, porencephaly, etc.), meningitis, encephalitis, and tumor, are the more important clinical causes. Only six (marked +) of the causes listed are known to be inheritable,

and these, except for cerebral aplasia⁵ are rare. Hardly ever is epilepsy inherited as a syndrome without the inheritance of other associated neurological disorders. For example, feeble-mindedness due to lack of cerebral development may be found to run in a family. That the patients also have fits is explained by the aplasia and neurological short circuiting; it is an associated symptom. Yet because the fit is dramatic the whole picture is called "epilepsy." Other inherited nervous diseases that may be accompanied by fits are tuberous sclerosis, Friedrich's ataxia, and cerebromacular degeneration. But these are so rare as to be numerically unimportant. On the whole probably less than 8 per cent of epileptics show an inherited factor as judged by a history of epilepsy in a relative. Epileptic individuals who do have epileptic close relatives should be advised against having children. The remaining 92 per cent cannot reasonably be advised against marriage (if they can find mates). More epileptics come from families burdened with migraine than from epileptic ancestors, and the taint is often carried latent in a "normal" person. Therefore, the idea of effectively eliminating epilepsy by sterilization and "eugenics" is preposterous.^{6,7} Given laboratory control and thousands of generations it could be done.

Epilepsy means merely "seizure," a vague term at best, but it is usually understood to signify *sudden, recurrent changes in consciousness, often preceded by a sensory warning (aura) and often followed by motor discharge through the muscles (convulsion)*. Penfield and Gage⁸ in an admirable paper on "Cerebral Localization of Epileptic Manifestations" say that under the heading of fits may be listed (besides convulsions) paresthesia, hallucinations of sight, visceral sensations, and autonomic phenomena. The list is so broad that there can be nothing typical about an epileptic fit, the essential being that *it is a disturbance of consciousness, overwhelms the victim suddenly and usually recurs in any one victim in a rather stereotyped pattern, or patterns*. In other words, each epileptic patient is likely to have his own special form of fit and to repeat it. He may have two or three which alternate; for example, it is common to have major seizures (grand mal) of one type interspersed with more frequent minor seizures (petit mal) perhaps resembling only the aura of the grand mal.

Thus it is difficult to differentiate epilepsy from other recurrent symptoms such as fainting (syncope), migraine (sick headache) and myoclonia. Syncope is often accompanied by a few convulsive jerks; migraine may have an aura and may begin entirely in the sensory sphere, but may change over into motor manifestations that anyone would call "epileptic." Moreover, fibrillary contractions, tremor, myoclonia, chorea, athetosis and convulsion form a series of muscular expressions of central nervous disorder that cannot be arbitrarily divided into those that are "seizures" and those that are not. One can talk of an attack, spell or fit of any one of them. But one talks of *epilepsy* only when there are *recurrent, rather similar attacks of disturbance of consciousness*.

Fits of a rudimentary sort may be elicited in the spinal cord; syncope and vasovagal attacks may be bulbar in origin; the diencephalon may discharge explosively giving rise to vasomotor, sudomotor and cardiac symptoms; and the forebrain with its many subdivisions gives rise to various sorts of seizures. Most attention has been directed to the cerebral cortex as the locus from which epilepsy usually arises. The conception is that a lesion in or near gray matter makes this gray matter more irritable than normal, lowers its threshold so that sudden, or slowly built up stimuli may cause a violent, disorderly neuronal discharge that we call a fit. The lesions may sometimes be actively irritating, as in the case of bleeding vessels, acute infections, growing tumors, or contracting scars. More often the lesion is more static, and seems by its mere contiguity to reduce the threshold of irritability of the adjacent gray matter; *e. g.*, old areas of fibrosis and gliosis following injury, slowly growing tumors, cysts of softening, and arachnoiditis. In the cerebral cortex this conception seems to hold true; much evidence has been accumulated by neurologists, surgeons and pathologists that focal lesions act as the starting point from which unbridled impulses spread to cause fits. They can only cause fits if they spread into comparatively normal tissue, for the neuronal discharge must be an exaggerated and explosive one that could not come from a badly damaged nerve cell. The wild impulses are excessive and disorganized, but in causing seizures they are probably acting through comparatively normal tissue.¹⁷

The evidence for this is extensive and well substantiated by operations on the brains of conscious patients. In the first place careful clinical histories have been compared with operative findings. Still more interesting are the results of electrical stimulation of the exposed brain in conscious patients. In normal animals convulsions may be brought on by excessive electrical stimulation of certain parts of the cerebral cortex, beyond the point of physiological response. Exploring the human cortex with an electrode at operation has located not only the motor area, where special movements are represented in the precentral gyrus, but areas from which synergic movements of the opposite side may be elicited, and movements of the head and eyes toward the opposite side. This particular movement has been elicited from several locations: area 6a in the frontal lobe, near the periphery of the occipital cortex, near the superior temporal, marginal and superior parietal gyri. It is interesting that this coordinated movement of the head and eyes turning to the side opposite the lesion is probably the commonest type of onset of a convulsion. Such movements may be precipitated by electrical stimulation of the cerebral cortex of an epileptic patient, and may lead to a spread of the motor spasm to other muscle groups with unconsciousness and general convulsion, just as in a spontaneous seizure. In fact, exploratory electrical stimulation may locate low-threshold "trigger points" at which the patient's typical attack may be set off.

When such a point is near the motor area (precentral gyrus or central sulcus) the attack begins *without aura*, the appropriate muscle group begins to twitch convulsively and then the convulsion spreads in an orderly way to other muscles. This *march* is observed by the patient and he *does not lose consciousness* until fairly late in the attack if at all. When the trigger point is in the postcentral (sensory areas) the attack usually begins with a localized numbness or tingling in a hand or foot, this spreads and focal motor phenomena appear usually simultaneously in both arm and leg, with less of the element of progressive march. In the occipital area the warning for the attack may be crude *lights*, red, blue or white followed by loss of consciousness and *general convulsion*. In the parieto-occipital region the lights may be flashing or mov-

ing, causing giddiness and even nystagmus, followed by unconsciousness and general convulsion. From lesions in the temporal gyri the general convulsion is often preceded by noises, hyperacusis, tinnitus or even music, which may be accompanied by vertigo or hallucinations of unpleasant odors. Tumors near the uncinate gyrus commonly cause an aura of bad smells or taste with automatic smacking movements of the lips before the convulsion. Thus much physiological knowledge has been corroborated on the human by surgeons using the electrode and by Nature using local lesions.

Lesions of the frontal lobe are particularly interesting. Since this is the largest association area of the brain without any receiving stations for special senses (as in the parietal, temporal and occipital lobes) one would expect little or no aura. This is the case: the patient usually begins his attack with a blank stare, losing consciousness at once, but not losing motor control, for he may then perform complex movements, walk about doing aimless things and mumbling. In more sudden attacks he may turn his head to the side away from the lesion, and then turn his whole body, even spinning around two or three times before falling in a general convulsion.

All this about cortical epilepsy, however, is rather special. It is particularly interesting because of its localizing value and because patients with cortical lesions are most open to surgical help. But the recent work of Gibbs and Gibbs⁹ shows that (in cats) the deeper structures where the rhinencephalon lies over the diencephalon give convulsions in response to electrical stimuli more easily than even the motor area of the cortex. It is as if certain tracts and cells here would set off a convulsive mechanism with greater ease than others. The fact that deep temporal lobe tumors are especially likely to be associated with convulsions is of interest in this connection. But the search for a "convulsive center" is illusory. There can be no "center" for disorganization or disintegration. Probably, because of special connections, easily traveled paths, or ease of conduction in certain areas, an electrode placed in such loci will more easily cause the unbridled activity we call a convulsion, than an electrode placed elsewhere. We know that stimulation of less organized brains is more likely to cause convulsions than stimulation of thoroughly organized ones; *e. g.*, the convul-

sions of childhood,¹⁰ and there are experiments showing that after injury the threshold for convulsions is lowered.¹¹ Myelination is quite incomplete in the human before the fourth year and convulsions can be easily precipitated in these years by almost any foreign element of excessive stimulation. This is perhaps because of less than normal spread; *i. e.*, *short-circuiting*. In chronic encephalitis, or postencephalitic states, there may be gliosis of the brain and the formation of connective tissue scars; cerebral hemorrhage and trauma may act in much the same way, and also the chronic degenerative diseases. It may be that reduction of the number of available association pathways for nerve impulses to travel is the important factor in all these extensive lesions. This, theoretically, could cause a "short-circuiting" of afferent stimuli making them discharge over efferent tracts without the normal delay caused by spreading through the wide association areas of the cortex.¹² Such short-circuited discharge might well be explosive and disorderly and cause seizures of various sorts. Other chronic processes, such as arteriosclerosis, senile degeneration, chronic arachnoiditis and porencephalic cysts, may also cause seizures by tissue destruction and this "short-circuiting" mechanism. Tumors and cysts obviously cause increased intracranial pressure and damage to the tissue, but the fact that tumors of the hindbrain rarely if ever cause convulsions¹³ and that convulsions are most common when the motor cortex is involved, indicate that there is direct irritation of motor nerve cells. It might be that these tumors interfere with circulation and cause local stasis with edema, anoxemia and softening, but such changes would cause death of nerve cells and the convulsive symptoms would soon cease; clinical experience shows that convulsions caused by tumors impinging on the motor area may occur over periods of several years.

It is probable that vasomotor abnormality in the brain as a primary cause of seizure has been overemphasized by some authors¹⁴; but that changes in cerebral blood flow may precipitate convulsions, is indisputable. There are six conditions on the list that obviously work through anoxemia of the brain. All of these six cause widespread anoxemia and convulsions. The first is Stokes-Adams syndrome in which, as reported by Mackenzie, if the heart block lasted for ten sec-

nds only, unconsciousness alone occurred; but if it lasted for seventeen seconds, there was also convulsion. The onset of paroxysmal tachycardia may also be attended by seizures. Pressure on the carotid sinus with the sharp fall in blood pressure may precipitate a convulsion, but sometimes the convulsion occurs without the fall in general blood pressure.¹⁵ The other two mechanisms that can be relied on regularly to produce convulsions are carbon monoxide poisoning and mechanical asphyxia, as in strangulation. In experimental animals it is always possible to produce convulsions by ligating the arteries that supply the brain, and also by limiting the oxygen that is inhaled. In patients having very frequent petit mal, Lennox^{16a} has shown that seizures can be induced by a degree of oxygen lack that will not affect normal persons, and also by an impending induced syncope. It is obvious, however, that these conditions that cause general cerebral anoxemia are not the ordinary causes of seizures as seen in epileptic patients. Gibbs and Lennox¹⁶ have shown that no *general* change in cerebral blood flow occurs before a fit. On the other hand, *local* areas of cerebral anemia may set off the neurological mechanism that causes fits¹⁷ and there is good histological evidence that many convulsions, including puerperal eclampsia, are due to vascular spasm in the brain.¹⁸ Some cases of Raynaud's disease and of angioneurotic edema are accompanied by seizures.

The effect of emotion and environmental stress upon epilepsy has long been recognized. Increased emotional stimuli¹⁹ especially if repressed, usually increase the number of attacks. Special situations may act as conditioned stimuli and set off fits that thus are practically conditioned reflexes.²⁰ Examples of this are common in practice and patients showing possible psychological factors should be studied intensively. For example, a young woman of twenty-one was referred to me in 1932. At the age of nine she had cranial trauma and two months later onset of convulsions. She has seen many doctors and had many treatments. A régime of high enemas at twelve did no good; a nine months' trial of dehydration at eighteen made her worse; "lutein" has helped her irregular menses, but has not affected her fits; luminal helped, but has been used excessively. Because the attacks began in the left leg and

because slight but distinct neurological abnormalities were noted on the left side, Dr. Wilder Penfield operated upon her at the age of nineteen and found adhesions over the right frontal lobe, excessive vascularity of the cortex and unstable arteries. These were actually observed in vascular spasm with concomitant anemia of the lower part of the motor cortex and convulsion especially in the left face.²¹ Removal of the "trigger point" in the cortex, where a weak faradic current precipitated a convulsion (right superior frontal convolution) caused temporary hemiparesis, but eventual diminution in number and severity of the attacks. Eighteen months later she went through a severe emotional experience, thereafter there were more "minor seizures"; many of these were probably anxiety states as no clouding of consciousness was observed. The emotional element was great. Since the age of ten she had been supervised meticulously, her varied and prolonged treatments had given her the "invalid habit," she was full of self-pity, said she was "utterly lonely" and could not mix with other girls or boys of her own age. She had had no regular schooling and could get no job.

To evaluate all the factors mentioned in this complex picture is difficult, but important, if one is to help this girl who is not only epileptic but hypochondriacal, psychoneurotic and drugged with luminal, coffee and cigarettes. Charting the factors helps a great deal to make the problem concrete (Fig. 180). This is a "life-chart" drawn to indicate the dynamic factors in the patient's history. Each arrow represents one of the factors in the etiology of the present problem; *i. e.*, the fit. The lines suggest by their weight the severity of the abnormality and by their length the duration. Obviously all the factors contributing to the "nervous load" are not equally important from an etiological standpoint, but by looking at the whole chart one gets an idea of the interaction of the different elements. Certainly the main abnormality, represented by the heaviest arrow, is the *cerebral cortical scar* present since the age of nine; this is the principal cause of the fits; it has been treated surgically in the most scientific manner; nothing more can be done.

The arteries of the brain were observed in spasm; there are other indications of *vasomotor instability*, but the poor

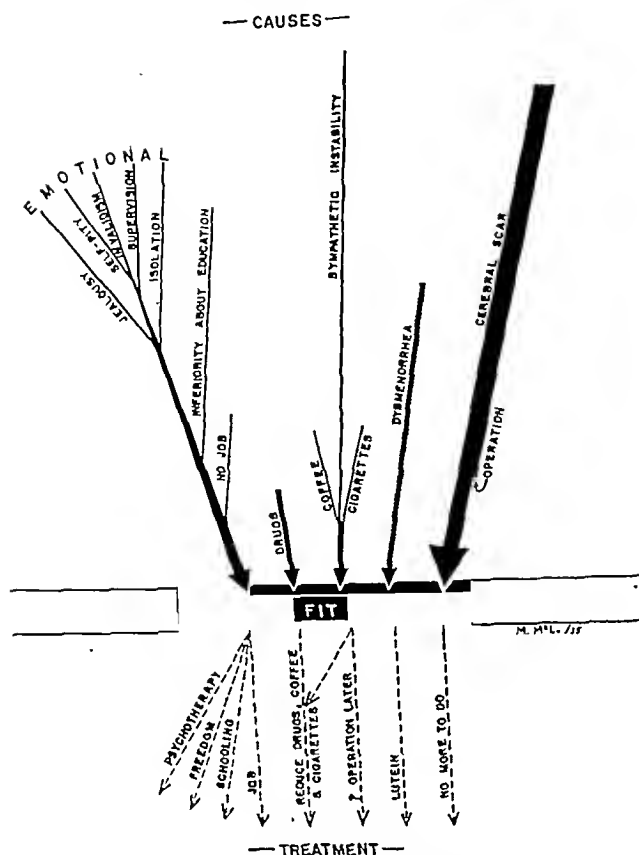

Fig. 180.—The diagram is drawn to bring together in the physician's and patient's minds the etiological factors in a dynamic way. Above are the various causes, indicated by arrows, converging on the patient at the time of examination. These arrows, great and small, make a burden too great for the patient's nervous system and a fit results. Obviously the main cause of convulsions in this case is the cerebral scar, a heavy burden for many years, hence represented as a long and heavy arrow. The operation improved the cerebral lesion and fits became fewer thereafter, hence the notch in the big arrow. The other arrows represent other pathological factors in the patient's life. These are individually of slight importance as compared to the cerebral lesion, but added together they constitute an important problem and probably act as the precipitating cause of many attacks. Below is shown what was done for treatment of each pathological cause. For the cerebral scar nothing more can be done. For the dysmenorrhea lutein was given. To counteract her vasomotor instability she was made to cut down on coffee, cigarettes and drugs (a sympathectomy might possibly be considered later). To improve her emotional instability, she is taken away from anxious supervision, given a job, schooling, and some psychotherapy. These are adjuncts to the surgical therapy, but they make this difference to the girl: she stops being an invalid, lives a practically normal life, is happy and has fewer fits.

general hygiene of the patient may be responsible for this, especially the excessive coffee and cigarettes. An operation to denervate the cerebral arteries by sympathectomy was considered, but it was deemed unwise to operate again upon her. General hygiene, physical training, reducing coffee and cigarettes, all have helped the vasomotor instability.

Luminal has been used for several years; for the last two years 3 grains per day had been given. She has been rather depressed and dozey from this and her eyes have often looked sleepy. This medicine was discontinued for a period of observation, during which general hygiene, both mental and physical, was emphasized. There was no increase in the number of seizures. *Lutein* has been found to help her painful and irregular menses; this has been continued.

The *emotional factors* are numerous. Taken singly they do not seem important; added together, however, they make a burden of anxiety, unhappiness and self-pity that is devastating; the patient was having no satisfaction out of life. It is here that one feels most hopeful about therapy. The patient needed schooling and training to give her self-confidence; she was taken from home and put under less fearful and more objective supervision. This resulted in a new feeling of freedom. A job was arranged for her part time. Psychotherapy was tried and gave her insight into what was being done for her, but otherwise it had little effect and was soon discontinued. It was the environmental treatment that helped most. During the past two years she has had only two attacks.

When such a "new deal" can be arranged for a patient, there is reason for optimism regarding the prognosis even in cases of "traumatic epilepsy." The fact that one has a scar in one's brain does not make convulsions a certain result. It is a case of summation of nervous load. When many of the factors indicated by the arrows impinge on the patient's nervous system at once, a seizure results. It is a case of the "camel's back" and many "straws." One cannot take away the scar which is the original and biggest part of the nervous load, but if the other straws are removed, the patient may well go on for years without a seizure. Symptomatically she may be "cured." And that is all the patient cares about.

CLINIC OF DR. G. P. GRABFIELD

PETER BENT BRIGHAM HOSPITAL

THE TREATMENT OF INSOMNIA

THE treatment of insomnia is a subject which can be considered from many angles. It seems wise to limit the discussion to certain phases of the subject, in order to avoid excursions into the realm of psychiatry. Texts of internal medicine do not recognize such a condition. It must be admitted that no clear, short definition can be stated. Yet all know what is meant by the term, though from an etymological point of view it simply means lack of sleep from any cause. It may be due to pain, discomfort, dyspnea, frequency, diarrhea, itching or any symptom that forces itself upon the sensorium. However, the usual idea of insomnia as a medical problem is that of sleeplessness unconnected with somatic symptoms. If sleeplessness is due to some definite cause, such as one of those enumerated above, treatment is necessarily directed to the relief of the underlying symptom. True insomnia, therefore, we may define as sleeplessness due to no underlying stimulation preventing sleep or awakening the sufferer. The condition may assume different forms.

First and most common is difficulty in going to sleep, second, awakening early and inability to sleep again, third, periods of wakefulness in the middle of the night and finally, a reversal of the sleep mechanism with wakefulness at night and sleep by day. The cause of the first three types usually is habit or some emotional disturbance either acute or as a manifestation of a psychoneurosis. The last, most distressing form is almost exclusively found in cerebral arteriosclerosis and usually is accompanied by other manifestations of senility.

Since it is axiomatic that the treatment of any symptom should be directed to its cause, and since the usual cause of

insomnia is either habit or a psychoneurosis, it is obvious that treatment must be directed against these underlying conditions. Many tricks have been advised to aid the sleepless sufferer; counting sheep, voluntary relaxation, lying in one position and various other methods of autohypnosis. While such methods may be successful in breaking bad sleeping habits or even in overcoming a superficial psychoneurosis, it is poor therapy to treat psychoneuroses by suggestion alone, and in every persistent case adequate psychotherapy applied by an expert is necessary. Often reassurance as to the harmlessness of sleeplessness is sufficient to break the vicious circle of wakefulness intensified by the worry of not sleeping and the consequent effect on the following day's efficiency. Certainly lying quietly in bed is often adequate preparation for the daytime tasks even though the hours spent in actual sleep be few. It is outside the scope of this clinic to discuss further the psychotherapy of insomnia. However, in connection with the foregoing, the indications for the use of hypnotic drugs may be concisely formulated. The following four indications for the use of soporific drugs seem clear:

1. Where sleeplessness can be foreseen as the result of an acute situation of short duration.
2. Where wakefulness is clearly due to an obvious cause, and the symptomatic relief will aid in the treatment.
3. Where the cause is unclear, but relief is urgently demanded, and no danger of masking night symptoms is present.
4. In the reversal of the sleep mechanism in cerebral arteriosclerosis.

The first group includes such situations as the near relatives of a deceased person before the funeral, the first night in the hospital and others that will readily come to the reader's mind. In the second group are such cases as discomfort from any of the causes previously enumerated. Even though the cause is unclear, and no definite disturbing symptoms are present, immediate relief of the third group of sufferers will aid subsequent therapy, even if the cause be psychic. Finally, relief in the fourth group demands the utmost care in the use of drugs to change the mechanism without intensifying it by the late action of the soporifics. This brings us to a further point to be remembered in the use of hypnotic drugs.

This consideration concerns the time and duration of action of the drug exhibited in relation to the intensity, duration and period of sleeplessness. It is well known that there are three types of insomnia, the commonest being difficulty in getting to sleep. "I stay up until I am sleepy, but getting ready for bed wakes me up, and I toss for hours," says the patient. The next tells of awakening in the middle of the night and lying awake for a period invariably longer to the patient than observation by the clock would indicate. And finally, there are the patients who awaken so early in the morning that they outdo the proverbial lark. Of course, any combination of these types may exist. The drug to be used in any given situation must be such as to combat the symptom of which the patient complains. It is all too easy and, unfortunately, too common, to give patients large doses of some momentarily fashionable or advertised hypnotic, when small doses of a judiciously selected drug would provide the relief desired. If we use the above criteria we may classify the hypnotics according to the rapidity and duration of their action. In general, these two properties are parallel. It is also an advantage to reduce the list to the smallest number that will serve. All hypnotic drugs have undesirable side actions in large doses or in susceptible individuals, and there must be included in any list a sufficient variety to allow for such idiosyncrasies.

Considering first those with rapid action over a comparatively short period of time suitable for patients unable to get to sleep, we find first of all paraldehyde and chloral both of which have stood the test of time. The obvious disadvantage of paraldehyde lies in its odor on the breath the following day, but this is often more than compensated by its efficacy and above all by the practical absence of toxicity. It must be remembered, however, that the combined use of morphine and paraldehyde is highly toxic. Chloral is undoubtedly the most useful of all the hypnotics and the cheapest. Given well diluted in water it produces sleep within an hour, and in proper doses (0.3–0.6 Gm., 5–10 grains) is entirely harmless even in heart disease. There is no doubt that in toxic doses it kills by its effect on the heart, but the fear of this side action has been engendered by the large dosage that has always been

recommended up to the last few years. None the less, it is not the hypnotic of choice in heart disease, though it may be used, if for some reason the barbitals and paraldehyde are contraindicated in a given patient. For quick action of short duration two of the barbiturate series recommend themselves. Pentobarbital (1-2 grains, 60-120 mg.) has proved very useful, and it may be that "evipal," a newer one of the series with a very rapid evanescent anesthetic action, when given intravenously, will prove useful as a short duration hypnotic with prompt action, when given by mouth.

Barbital itself is still the most satisfactory drug, where more prolonged and less prompt action is desired. In all these drugs both intensity and duration of action are increased with increasing doses. If, therefore, more than 0.6 Gm. (10 grains) of barbital is found necessary to produce the effect desired, another drug should be used. Comparable to barbital but of another chemical constitution is "sabromin," considerably more expensive than barbital but with prolonged effects. Sulphonethylmethane has fallen into disuse on account of the long period before it acts and because of its prolonged stay in the body. However, these very qualities can be utilized in selected cases. It is usually effective five to seven hours after administration and is particularly useful in the second group of patients. Its action, however, is prolonged, and it may leave a certain amount of drowsiness the next day. Furthermore, repetition over a comparatively short period, even in ordinary doses, may lead to liver damage. In occasional selected cases for short periods it may be extremely useful, especially in supplementing the action of some of the shorter acting drugs. Thus the combination of barbital with sulphonethylmethane given an hour or two before bedtime may prove more satisfactory than double the dose of barbital for producing a deep sleep throughout the night. This evidence of synergism suggests that other combinations might prove equally useful. The unfortunate one between paraldehyde and morphine has been mentioned and another between chloral and alcohol is well known, even to the underworld, in the form of "knock-out drops." Synergism between the hypnotics and antipyretics (analgetics) has been fairly well studied in some instances. This should be utilized when pain

or discomfort is associated with insomnia. While the anti-pyretic drugs of the types, acetyl salicylic acid, amidopyrine and acetphenetidine have almost no hypnotic actions, the soporifics discussed have equally little effect on pain. Yet combinations of these two groups of drugs enhances the effects of each. In this connection it is well to remember that both morphine and codeine are inefficient hypnotics as compared with the drugs discussed. Finally, on certain occasions sleep is disturbed, largely by motor restlessness, "the fidgets," not directly associated with cerebral activity. Under such circumstances phenobarbital ("luminal") and the bromides are most useful, but their effects are prolonged on a comparatively low level of intensity. Both are poor hypnotics in the strict sense of the term and produce their quieting effect by their depression of the motor side of the central nervous system; neither should be used as simple soporifics.

Care in the selection of the soporific agent in relation to the exact symptomatology will yield excellent results. Only a small number of the vast array of sleep producing drugs on the market need be in the armamentarium of the physician. Careful clinical observation of all the possibilities of a few drugs is a suitable problem for study in private practice. Laboratory research is active in this field, but it is to be hoped that careful clinical observation checking careful pharmacologic experiment will prevent the present increase by geometric progression in the numbers of hypnotic drugs varying but little from the standard and offering no real advance in therapeutic efficiency.

CLINIC OF DR. RICHARD M. SMITH

CHILDREN'S HOSPITAL

ABDOMINAL PAIN IN CHILDREN

ABDOMINAL pain is one of the most frequent conditions in children for which the physician is consulted. The pain may be acute and seen in a first severe attack or chronic and encountered after many recurring episodes of moderate and varying intensity. The first severe acute attack of pain is often an emergency in the sense that it requires an immediate decision in relation to the necessity for surgical intervention. Too great emphasis cannot be placed upon the requirement for superior surgical technic when an operation is indicated, but it is to be remembered also that a high degree of professional skill is needed to elicit and interpret correctly the history and physical findings. Despite the urgency of the situation a careful study of the patient should be made and all possible explanations for the pain should be considered. There must be the exercise of sound judgment for improper treatment, based upon an incorrect diagnosis, may result in the death of the child. When there have been repeated attacks of pain in the abdomen the emergency may be less acute but the difficulty in diagnosis even greater.

In dealing with children as contrasted with adults there are certain things which need especial consideration. The history of any illness is of great importance but it is difficult to obtain a reliable history of an illness in a child. In infants and young children the story must be obtained from a parent or nurse. One should ask simple questions which can be answered briefly—directed toward securing exact information if possible. It is easy for a lay person to give an interpretation of facts instead of the facts themselves. Sometimes a clear description of what has happened is given by the mother or nurse. Frequently, however, the account is confused by a

limited power of observation or by extreme apprehension and an exaggerated emphasis on trivial matters. One needs to consider the temperament of the person who is giving the history. Familiarity with the family is of great assistance. When the history is obtained wholly or in part from the child one must remember the limitations of the informant. Children rarely express themselves with precision. Usually they complain less than adults and often will talk very little when they are sick. Crying may be the only presenting symptom. Serious disease within the peritoneal cavity may exist without complaint of abdominal pain either because as in infants speech has not yet been acquired or as in young children the ability to localize pain has not yet been developed. Pain apparently in the abdomen may be local discomfort caused by disease elsewhere in the body. Despite the handicaps under which one works it still remains true that the history is of prime importance.

Another consideration to be constantly borne in mind in working with children is the frequency with which the pathologic condition is dependent upon some congenital anomaly. Such anomalies are not uncommon in connection with the group of diseases which are under discussion.

Pain in the abdomen may be caused by disease or disturbed function

1. of some part of the gastro-intestinal tract.
2. of some other abdominal viscus or structure.
3. in some other part of the body and the pain referred to the abdomen.

I. Abdominal pain caused by disease or disturbed function of some part of the gastro-intestinal tract.

Congenital hypertrophic stenosis of the pylorus.

Intussusception.

Intestinal obstruction.

Appendicitis.

Ulcer of stomach or duodenum.

Colitis.

Spastic colon.

Indigestion—"colic" in infants.

Congenital Hypertrophic Stenosis of the Pylorus.—

This is a condition the first symptoms of which appear dur-

ing the early weeks of life, rarely beginning immediately after birth. Crying is the obvious expression of pain. The pathologic finding consists of a stricture, partial or complete, at the pylorus, due to an hypertrophy of the circular muscle fibers and their replacement by firm fibrous tissue. The presenting symptom is vomiting of increasing severity and projectile in character. Constipation is an early feature, becoming more marked as the obstruction increases. The bulk of the fecal content decreases until the stools are composed entirely of intestinal secretions with no true fecal residue. There is stationary or loss of weight. Physical examination reveals peristaltic waves in the upper abdomen traveling from left to right (gastric) and a tumor palpable at the pylorus. These findings are most easily elicited just after a feeding followed by vomiting. Often the tumor is felt easily, but at times repeated examinations are necessary. The treatment is surgical and should be instituted as soon as the diagnosis has been established. If the infant shows marked dehydration intravenous and subcutaneous fluids should be given before operation. The prognosis is favorable if the operation is performed by a surgeon with experience in this particular procedure and has not been too long delayed.

Intussusception.—The history is of particular importance in this condition. An infant, previously well, often breast fed, has sudden severe cramp-like pain in the abdomen evidenced by a sharp cry and by drawing up of the legs upon the abdomen. Usually vomiting occurs promptly and shortly the baby passes a stool containing blood and mucus. Sometimes there is no blood in the stool or even there may be no bowel movement. There may be recurrences of the pain at frequent intervals with or without vomiting. If seen soon after the first attack the physical examination may be entirely negative, but there may be a marked degree of shock. Eventually a sausage-shaped tumor is palpable in the abdomen. Rectal examination may reveal the head of the invaginating portion of the intestine often just within the anal sphincter. The examining finger will usually show bloody mucus. Roentgen-ray examination without barium may show the point of obstruction and is useful in confirming the diagnosis. The treatment is surgical. The prognosis depends upon the time

at which operation is performed. If done early it is good; if late, the risk is greatly increased, rising directly with the time between the onset of symptoms and the operative interference. It is not desirable to try reduction of the intussusception with enemata.

Intestinal Obstruction.—We shall consider here only those instances in which obstruction is due to mechanical causes. Adhesions dependent upon a previous inflammatory process in the abdomen or secondary to a surgical operation may produce a similar picture. There may be complete or partial atresia of almost any part of the gastro-intestinal tract or other developmental defects such as incomplete relation of the cecum. Except when complete obstruction occurs the symptoms may be absent for many months or even years, or may be intermittent in character. Vomiting is the outstanding symptom. Pain is present in greater or less degree. The stools become scanty, depending upon the degree of the obstruction. There is usually abdominal distention with visible peristalsis. Dehydration may be extreme if the vomiting is severe. Roentgen-ray examination without barium often furnishes conclusive evidence and localizes the point of obstruction.

Appendicitis.—Appendicitis is a fairly common disease in childhood but is unusual in infants. Recurring attacks are frequent. Often the diagnosis is missed and the symptoms explained on the basis of indigestion. The striking feature of the condition as it occurs in children is the fact that a severe pathologic condition may be present with very slight symptoms and few physical signs. In over one half of the children admitted to the Children's Hospital for appendectomy the appendix had perforated when first seen (Hudson).

The etiology of appendicitis in childhood is not different from that in adults and need not be discussed in detail. It should be borne in mind, however, that true appendicular colic is not unusual in children associated with and dependent upon an inflammatory condition in the colon.

A typical history is as follows. A child who has been previously well is nauseated and vomits perhaps once or possibly two or three times. Associated with the nausea and usually before the vomiting there may be some abdominal pain,

but frequently it is not severe or is absent and often is of short duration. Sometimes pain occurs without vomiting. Movements of the bowels may be normal. The symptoms may entirely disappear at the end of a few hours and the child appear perfectly well, but if seen at the end of this period the physical signs of appendicitis may be present. Not infrequently the attack is so mild that no physician is called and recovery takes place. It is only when a child is seen in subsequent and somewhat more severe attacks that a presumptive diagnosis in relation to the previous attacks can be made. Occasionally the pain may be very severe and vomiting may be persistent, but this history is the exception rather than the rule. On physical examination the children do not appear to be very sick. There is a slight elevation of temperature, frequently not above 100° F. by rectum, or may even be normal and a moderate polymorphonuclear leukocytosis. It is possible to have a gangrenous appendix and a normal white count. Examination of the abdomen shows slight tenderness and a little spasm usually located in the right lower quadrant of the abdomen, sometimes in the right rectus muscle. True spasm, no matter how slight, should always be considered of pathologic significance. Pressure over other parts of the abdomen, especially over the left lower quadrant, may cause pain in the right lower quadrant. Rectal examination is important and frequently elicits a tender mass high up on the right just below the brim of the pelvis.

There are a number of anatomical considerations which modify materially the physical signs of appendicitis in childhood and these should be constantly borne in mind. The cecum, and therefore the appendix, is freely movable because of the long mesocecum. As a result, the appendix may be located in other portions of the abdominal cavity than the right lower quadrant. It may be on the left side instead of on the right. The appendix itself is also longer than it is in the adult and this adds further to its variety of location. When the appendix extends into the pelvis, as is frequently the case, there may be no physical signs in the abdomen. The diagnosis can be made only by rectal examination. In pelvic appendicitis not only are there no physical signs in the abdomen but there is practically no abdominal pain, but there is

discomfort on voiding or on emptying the bowel. The local inflammatory process may produce diarrhea or because of the pain there may be constipation or retention of urine. The appendix, because of its additional mobility, may be situated in the right flank and outside the cecum with the cecum over it and in front. The diagnosis, under these conditions, may be confused with an acute infection of the kidney, or if the inflammatory process extends downward, tenderness may be present just above the iliac crest. The appendix may be behind the cecum and the ileum and extend inward. This is a particularly dangerous situation because of the likelihood of general peritonitis developing.

A diagnosis of appendicitis should never be made simply on the basis of a local examination of the abdomen. It is important to obtain a careful and accurate history and to make a complete physical examination.

Ulcer of Stomach or Duodenum.—Ulcerations in the upper portion of the gastro-intestinal tract are not common in children but they do occur, and should be kept in mind in making a differential diagnosis in abdominal conditions. The vomiting of blood or blood-tinged mucus is of particular significance.

Colitis.—Ulcerations in the colon are very common in children. They may be dependent upon infection with one of a variety of organisms of the dysentery group. Tuberculous colitis occurs in rare instances. The onset of colitis may be very sudden with high temperature, convulsions, and marked prostration. Diarrhea may be absent for several days. Vomiting may be a prominent symptom. Pain may be slight or severe. Physical examination of the abdomen may be negative. One should remember the possibility of colitis in any acutely ill child when the diagnosis of some other condition is not clearly established. A culture from the stools is necessary for confirmation of the diagnosis.

Spastic Colon.—A spastic colon is usually associated with a history of long-standing constipation. There may be recurring attacks of abdominal pain, often with vomiting and elevation of temperature. Physical examination reveals abdominal distention of variable degree and it is usually possible to palpate the enlarged colon filled with hard fecal masses.

A barium enema, especially if observation is made on the fluoroscopic screen during the injection, shows an enlarged colon. There is sometimes resistance to complete filling, particularly at the flexures, where fecal residue has accumulated. Emptying of the colon after the enema may be incomplete and the haustral markings obliterated or reduced in depth.

Indigestion.—Under normal circumstances the processes of digestion go forward without our conscious knowledge and without producing any uncomfortable sensations. Due to a variety of causes, however, stimuli may be sent forth from the digestive tract, which cause mild discomfort or severe pain. When one has abdominal pain from this cause we say it is due to indigestion or colic. This diagnosis is difficult to make on the basis of positive evidence and is to be accepted only after all other possible causes of the symptoms have been eliminated.

A recent medical graduate in discussing his new experiences in practice outside of the hospital said that he had not yet seen a single case of unrotated cecum but that he had encountered numerous infants with "colic," and nobody had ever told him anything about it or what to do for it.

Colic is a term used to describe a condition seen in infants, characterized by pain in the abdomen associated with the digestion of food. Infants with colic are very fussy and restless and sleep poorly. Often they cry vigorously, especially at night. They are the babies who furnish the basis for many jibes at the solicitous father who walks the floor and the opportunity for the patent medicine vendors to dispose of "soothing syrups." Colic is seen most often in infants under three months of age. It often recurs at the same hour of the day or night.

It is not always easy to find out why some babies have colic. It is dependent upon a variety of conditions. Improper food is blamed most frequently by parents, but is the important factor less often than matters of hygiene and technic of feeding. In breast-fed babies the food may be unsuitable because the mother is tired or worried or of a temperament which makes lactation difficult. The attack upon colic, under these circumstances, should be directed toward establishing a better regimen for the mother but success is not easily attained.

In the bottle-fed baby some modification in the formula may be desirable, but if the food has been properly selected in relation to essential elements and their proportions and is adequate in amount, colic from this cause is rare. Most bottle-fed babies with colic are the victims of poor management. The feedings are given irregularly, the routine of bathing and care is haphazard, and attention is given to the point of fatigue. Food is not digested well because the processes of digestion are never allowed to proceed under normal undisturbed conditions. Sometimes the technic of giving the bottle is such that air is swallowed in large quantities, or the baby has to suck so hard as to become fatigued, or some of the other many possible errors are committed. The approach to the problem of treatment should be first to go over carefully the content of the food to satisfy oneself that it is correct, then to discuss in detail the routine of the baby's life. A long process of education may be necessary to bring about the proper daily care. Sometimes before relief of the condition is accomplished it will be necessary to introduce into the home a new person to whom the entire care of the baby is entrusted and who will carry out directions accurately. A demonstration by a short period of hospitalization is often effective. As a rule, a "colicky" baby is cured at once when placed on hospital routine, even when the food remains the same as that which was given at home. Relief of distress at the time of an attack of colic is usually possible by the giving of an enema and administering a small amount of warm sodium bicarbonate solution (1 drachm to 8 ounces of water) by mouth. Heat and mild massage to the abdomen is also helpful. It hardly needs to be emphasized that colic should be diagnosed only by exclusion of other pathologic conditions. One sees an infant crying hard with legs flexed on the abdomen, without fever—the question which presents itself for an answer is why? One must be satisfied that no other condition is present before assuming that the baby has colic.

II. Abdominal pain caused by disease or disturbed function in some abdominal viscus or structure other than the gastro-intestinal tract.

Diseases of the urinary tract.

Liver and gallbladder disease.

Pancreatitis.

Tumors.

Tuberculosis.

Infection—nontuberculous.

Purpura.

Allergy.

Diseases of the Urinary Tract.—Nephritis rarely causes abdominal pain. Acute infection of the kidney, on the other hand, is one of the common conditions giving rise to this complaint. Physical examination may reveal tenderness and spasm at the costovertebral angle and often the kidney is palpable. The diagnosis of urinary tract infection is confirmed by the finding of pus in the urine. One must remember that not uncommonly the underlying pathologic lesion is a congenital anomaly which interferes with the free passage of urine at some point between the kidney and the external urinary orifice. There may or may not be an associated hydronephrosis. Careful studies with cystogram, intravenous, or retrograde pyelography are necessary to determine the exact character of the lesion and indicate the appropriate treatment, either medical or surgical.

Renal stones are quite common in children and not rare even in infants. Pain may not be a prominent symptom. Occasionally stones in the bladder occur in children.

Renal tumors may often attain a large size beyond the stage where operative removal is possible without giving rise to pain.

Perinephric abscess is rare in children.

Liver and Gallbladder Disease.—Acute catarrhal jaundice may cause pain in the right upper quadrant of the abdomen. Gallbladder disease, with or without stones, is not common in children. Other diseases of the liver causing pain are rare. Chronic passive congestion dependent upon cardiac decompensation is often very painful.

Pancreatitis.—Pancreatitis is very rare in children. Occasionally the pancreas is affected in epidemic parotitis (mumps).

Tumors.—A variety of tumors within the abdominal cavity may be found in children. Some of these give pain only when they have reached a large size, causing tension upon the capsule of an organ or have metastasized to glands, particularly

the retroperitoneal glands, and cause pain by the same mechanism. An ovarian cyst, often with a pedicle which becomes twisted, may cause severe abdominal pain and present, on examination, the findings of an acute surgical abdomen.

Tuberculosis.—Tuberculous peritonitis and adenitis are both encountered much too frequently in infants and children. Peritonitis is more common under three years of age. Obstruction is often a prominent feature. The onset may be insidious and the condition be far advanced before there are sufficient symptoms to lead the parents to consult a physician. Adenitis may also be unsuspected for a considerable time and if the glands in the right lower quadrant are involved, as is often the case, the differential diagnosis from appendicitis may be difficult and sometimes is made only at the time of operation. Except when an operation cannot safely be postponed, the tuberculin test is of great assistance in diagnosis and if the condition is of long standing the roentgen ray may disclose beginning deposition of calcium.

Nontuberculous Infections of the Abdomen.—Peritonitis and adenitis due to organisms other than the tubercle bacillus are common in children. Thrombophlebitis of the portal vein or some of its tributaries is not rare. Most frequently these infections are associated with infection in some other part of the body, primarily of the respiratory tract, or they may be the first presenting sign of a general septicemia or as the only evident focus of infection. It is important to appreciate the significance of this association because of the influence upon treatment. Attention should be directed primarily toward the general infection. Peritonitis of this origin is better treated by conservative methods than by immediate operative interference. In adenitis the glands themselves require little consideration.

Purpura.—Not infrequently the abdominal lesions of purpura give rise to acute abdominal pain. A careful history with the finding of other evidences of purpura must be relied upon to establish the diagnosis.

Allergy.—Abdominal symptoms in allergic conditions are not rare. These symptoms may be the only manifestation of the disease at the time of an acute attack or even of a chronic state, but again the history, both familial and individual, to-

gether with other allergic symptoms, should serve to differentiate this form of allergy.

III. Diseases in which there is pain referred to the abdomen.

Respiratory tract infections.

Rheumatic fever.

Diabetes.

Roseola infantum.

Lead poisoning.

Spinal disease.

Intracranial disease.

Respiratory Tract Infections.—Mention has already been made of the abdominal complications of respiratory infection. There are also instances in which there is no specific lesion within the abdominal cavity but in which abdominal pain occurs. Pneumonia is a classical illustration. Physical examination may be confusing for there may be few or no signs in the chest but tenderness and spasm of the abdomen. Spasm of the abdominal muscles, which is caused by disease above the diaphragm, relaxes with firm steady pressure but increases if due to disease within the abdominal cavity. A roentgen ray of the chest may reveal early pulmonary congestion not detected by percussion and auscultation.

The toxins liberated from infectious processes in the respiratory tract may act upon the muscles of the intestines, producing enterospasm, or upon the gastric and intestinal secretions, causing "indigestion."

Rheumatic Fever.—Carditis associated with rheumatic fever may cause abdominal pain. The other signs of rheumatic fever should prevent a misinterpretation of this symptom.

Diabetes.—Diabetic acidosis may be accompanied by severe abdominal pain. The explanation for this symptom is not clear.

Roseola Infantum.—One of the important symptoms of roseola may be abdominal pain. The age of the patient, the high temperature, and the normal physical examination are of assistance in the diagnosis.

Lead Poisoning.—Occasionally in children lead poisoning

may cause cramplike abdominal pain associated with constipation. This is not as commonly the case as in adults.

Spinal Diseases.—No patient with abdominal pain should fail to have a careful examination of the spine. The roentgen ray may reveal osteomyelitis or tuberculosis.

Intracranial Disease.—Rarely children with intracranial disease or edema associated with renal disease complain of periodic abdominal pain.

With these conditions in mind, how should one approach the diagnosis in an infant or child who complains of abdominal pain or presents symptoms suggestive of disease within the peritoneal cavity? It is essential first to remember what has been said of the importance of the history. Not infrequently a correct diagnosis is dependent upon an accurate history. The age of the patient must be given consideration because of the relative frequency of congenital abnormalities in infants. A first acute attack often presents less of a problem than recurring attacks occurring over a long period of time.

The physical examination will be greatly facilitated if one can gain the confidence of the child. Time spent in accomplishing this is amply rewarded because of the difficulty of getting reliable signs in a child who is resisting examination. Much information is revealed by inspection and may be obtained while the history is being taken and one is becoming acquainted with the child. When one palpates the abdomen one should be sure to have warm clean hands. The movements should be slow and gentle. The child should be engaged in conversation if possible. Observation of the child's face will often indicate pain more definitely than replies to direct questions. One should inspect the abdomen for distention or visible peristalsis and examine for free fluid, palpable or enlarged viscera, for abnormal masses, tumors, or accumulated feces. The character of these masses is important. Tenderness or spasm, even if very slight, is of real significance. The relaxation of spasm under slow steady pressure indicates disease above the diaphragm rather than in the peritoneal cavity. Palpation of the abdomen is unsatisfactory when the bladder is full.

One should not be satisfied with the local examination, but make a complete physical examination. The lungs deserve

especial consideration. The roentgen ray may reveal early signs of pneumonia not detectable by auscultation and percussion. In examination of the heart one should look carefully for the sign of pericarditis. Search for signs of respiratory disease should include investigation of the nasal accessory sinuses and the ears. The skin may show petechiae or other indications of a general infection. Rectal examination should not be omitted but should be done after all other procedures have been completed.

Certain special examinations may be indicated and in children with a history of recurring attacks of abdominal pain should not be overlooked. The blood may show leukocytosis, abnormal cells, reduced platelets, or stippling of the erythrocytes. The urine may contain pus or blood or crystalline elements of significance. The intradermal tuberculin test is essential in the consideration of a diagnosis of tuberculosis. Intravenous and retrograde pyelography gives valuable information about kidney structure. Roentgen-ray examination of the abdomen may show renal calculi, calcified glands, intestinal obstruction or tumor, and after barium ingestion or enema abnormal condition of the stomach, intestine, or colon. The roentgen ray of the long bones may establish the presence of an excessive deposit of lead.

Not all of the possibilities to be considered in the diagnosis of the cause of abdominal pain in children have been considered but the more important diseases have been mentioned and some indication given of the technic to be followed in reaching a correct explanation of the signs and symptoms. The process is one of diagnosis by exclusion and should be subject to periodic review unless the symptoms cease under medical treatment based upon a provisional diagnosis or after corrective surgical interference.

CLINIC OF DR. EUGENE B. FERRIS, JR.

THE THORNDIKE MEMORIAL LABORATORY, SECOND AND
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY
HOSPITAL, AND THE DEPARTMENT OF MEDICINE, HARVARD
MEDICAL SCHOOL

THE CLINICAL SIGNIFICANCE AND TREATMENT OF VERTIGO, DIZZINESS, AND RELATED SYMPTOMS

THERE is a tendency among physicians and patients to use the term vertigo to include such symptoms as giddiness, dizziness and faintness. Hughlings Jackson¹ pointed out long ago, and Symonds² has more recently stressed the fact that patients do not accurately describe their sensations through the use of such loose terms. Our experience in this clinic with patients who complain of attacks which include such sensations has led us to separate these patients into two distinct groups as regards their subjective feeling.

One group of patients complains of attacks including sensations which may be classified as true vertigo. The patients are conscious of a subjective feeling that their environment is moving about them or that they are moving about their environment. These subjective movements follow an orderly pattern which in individual patients is similar in different attacks. The patient is able to describe accurately either the direction of, or the type of movement.

The other group, which is a much larger one, consists of patients whose subjective sensations are vague and much more difficult for them to describe accurately. These sensations are variously described as vertigo, giddiness, dizziness, weakness, unsteadiness, dimness of vision, and faintness. The multiplicity of symptoms of which these patients complain is probably due to their inability to find a term which will adequately describe their sensations. A sensation of movement of the body or of other objects sometimes occurs, but the movement is not orderly or in a direction which the patient

can describe. Such sensations are best described by the terms dizziness or faintness, and belong to that syndrome which, when severe, terminates in syncope. For practical purposes these subjective sensations may be looked upon as "pre-syncopal" in nature.

Thus in analyzing the subjective complaints of such a patient, it is important to determine whether he suffers from true vertigo or from symptoms of a syncopal nature. There are a few distinctive features which serve to differentiate these two symptom complexes in a majority of instances in addition to the patient's description of his subjective sensations. The most important differential point is that vertigo is rarely, if ever, accompanied or followed by syncope or a feeling of faintness. Attacks of vertigo occur as frequently when the patient is lying down as when he is upright, and the attack is not influenced by orthostatic changes. On the other hand, dizziness and syncope occur when the patient is in an upright standing or sitting position, except in a few isolated instances, and are relieved by lying down. Nystagmus is common with vertigo and rare with syncope. Nausea and vomiting occur with syncope but more often accompany vertigo.

VERTIGO

I should like to reemphasize that the sensation of vertigo is a subjective feeling in which the patient seems to move about his environment or the environment seems to move about the patient in a definite pattern. The attacks are usually identical in a given individual. Depending on its severity, the attack may be accompanied by nausea, vomiting, pallor and sweating, and the patient may stagger or fall to the ground without losing consciousness. The attacks appear to be self-limited as to duration and may last from a few minutes to several hours. In rare instances the vertigo is almost continuous.

It is probable that the mechanism of vertigo is reflex in nature and that the cerebellum plays a major rôle in the production of such a syndrome. Thus, it is apparent why sensory impulses from the semicircular canals and from the eye, both closely connected reflexly to each other and to the cerebellum, should cause vertigo so frequently. Less commonly, lesions of the cerebellum, of the eighth nerve, of cerebellar tracts in

the brain stem, and of other afferent pathways leading to the cerebellum may cause this symptom complex.

Aural and Ocular Vertigo.—The most common causes for vertigo are automobile or train sickness and sea sickness. The former is an ocular type of vertigo and is probably brought about by rapidly following moving objects with the eye. The vertigo that sometimes occurs in individuals who look from high places is also said to be ocular in type. Sea sickness is largely initiated in the semicircular canals but may be due, in part, to ocular reflexes as well. The nausea, vomiting and vertigo caused by whirling around or swinging is of a similar nature.

Aural vertigo commonly occurs from irritation or increased pressure in the semicircular canals resulting from hemorrhage, infection, and from positive or negative pressure in the canal due to middle ear disease. Irritation or infection in the external canal or middle ear may also cause vertigo.

Ménière's Syndrome.—Dandy³ and others⁴ have shown that this condition is fairly common and have suggested that the term Ménière's syndrome is more appropriate than the term, Ménière's disease. Ménière's disease is not well defined clinically and is variously used to denote hemorrhage into the labyrinth, labyrinthitis, or to include various other types of aural vertigo. As Dandy points out,³ of the cases originally described by Ménière, the only one examined pathologically was found to have been suffering from what appeared to be acute purulent labyrinthitis.

The typical Ménière's attack is one of sudden vertigo which, when severe, is accompanied by nausea, vomiting, pallor and sweating. Unilateral deafness is also present, and is progressive. Tinnitus on the affected side may occur only during attacks or may be present constantly. Nystagmus is usually present during the attack. The patient may fall to the ground, but rarely, if ever, does he lose consciousness. The attacks may occur at any time, either in the horizontal or upright position and even during sleep. The duration of attack varies from a few minutes to several hours. In an individual patient the attacks may vary in severity, but the severe ones are quite similar as to duration and symptomatology. Sudden movements of the head, ocular stimulation

from watching the movement of crowds or riding in trains or automobiles, unusual noises and fatigue, or emotional reactions may be precipitating factors. For many attacks no exciting cause can be ascertained. The term, pseudo-Ménière's syndrome, is used by Dandy to describe attacks of a similar nature in which deafness is not present. Most otologists feel that Ménière's syndrome results from middle or inner ear disease, but Dandy feels that it is caused rather by functional abnormality of the eighth nerve or its vestibular branch.

Vertigo Associated with Intracranial Lesions.—Neville⁵ and Symonds² have recently discussed the various intracranial lesions which may produce vertigo. Suffice it to say that true vertigo may result from lesions in the cerebellum, pons, cerebrum, and cerebellar tracts as well as from increased intracranial pressure. Such lesions may be in the forms of tumor, abscess, hemorrhage or thrombosis, particularly of the posterior cerebellar artery, multiple sclerosis, arteriosclerosis, and encephalitis. These lesions may be recognized by localizing manifestations other than vertigo. Cerebellopontine angle tumors, when associated with unilateral deafness and tinnitus, may closely simulate Ménière's syndrome, but the attacks are milder in nature and other cranial nerves are also involved.

Vertigo Due to Neurosis.—Mendel⁶ and Leidler⁷ describe true attacks of vertigo which occur in patients having all the characteristics of a neurosis and in whom no organic cause can be found. The vertigo tends to be present constantly and is not accompanied by deafness or tinnitus. Such patients do not respond to any form of treatment.

Other Causes of Vertigo.—Vertigo may be caused by "toxic" agents such as alcohol and may be a symptom of uremia. It is particularly prone to occur in enteric infections and gastric upsets in children.

Treatment of Vertigo.—Treatment largely resolves itself into specific therapy of the disease causing this symptom. In acute diseases of the middle ear and labyrinth, the vertigo may disappear when the infection subsides. In chronic disease of the middle ear local treatment may be of aid, but it is not entirely satisfactory. For persistent attacks of vertigo, general measures which tend to depress or alter reflex activity

should be carried out. Sedative drugs such as bromides and barbiturates, as in epilepsy, may lessen the severity and frequency of attacks. When psychic factors and fatigue play a rôle, proper corrective measures are of aid. Furstenberg, Lashmet, and Lathrop⁸ advocate keeping such patients in a state of negative sodium balance and acidosis by means of administering 9 Gm. (540 grains) ammonium chloride daily with a low sodium diet. They have reported good results in 12 cases. Dandy³ and Coleman⁴ have obtained symptomatic cures in 42 patients suffering from Ménière's syndrome by surgical section of the eighth nerve. Such an operation appears to be safe in the hands of a competent surgeon, and should be advocated for patients suffering from repeated attacks of vertigo, tinnitus and unilateral deafness in whom intracranial lesions have been ruled out and other treatment has failed.

During the actual attack of vertigo, care should be taken to prevent the patient from injuring himself by falling. An ice-bag should be placed on the affected side and sedatives administered. The head should be placed in a position most comfortable to the patient. The attacks are self-limited and the patient soon learns when relief is to be expected.

DIZZINESS AND SYNCOPE

Observations and studies in this clinic^{9, 10, 11} on a large number of patients complaining of attacks of syncope and related symptoms have demonstrated that the subjective sensations which precede fainting are similar, regardless of the cause, and can be clearly differentiated from vertigo. If true vertigo can be ruled out, dizziness, faintness, and similar terms represent symptoms which precede syncope; therefore, a discussion of such symptoms necessarily includes one of syncope also. The patient's description of such presyncopal sensations varies with the severity of the symptoms, with the nearness to the state of unconsciousness, and with the duration of symptoms before unconsciousness occurs; however, all sensations have certain definite characteristics. The patients variously describe their feeling as dizziness, weakness, faintness, unsteadiness, of "things going black before the eyes," a feeling as though they were going to faint or fall asleep, and "weak-

ness in the stomach." There is no subjective movement of the patient or his environment in a definite pattern as is encountered in true vertigo. The symptoms usually occur when the patient is sitting or standing, and are relieved by his lying down. Rarely do they occur when he is in a reclining position. Being an early manifestation of fainting, such dizziness is of course encountered among a great number of subjects in whom the syndrome does not progress to unconsciousness.

The mechanism and cause for various types of syncopal attacks have been extensively investigated by Weiss and his coworkers in this clinic^{9, 10} and a summary of the entire subject by Dr. Weiss can be found in the current Oxford System of Medicine.¹¹ I shall discuss briefly only the most important causes for such symptoms.

Vasovagal Syncope.—The commonest cause for dizziness is that associated with vasovagal syncope,¹² which includes ordinary fainting attacks. Such attacks nearly always occur in the upright position, and are relieved by lying down. During typical attacks, the heart rate is often slow and the blood pressure low. The patient is pale, sweats profusely, and the skin and extremities are cold and clammy. In individual instances, any of these manifestations may be absent. The attack lasts from one half to two minutes and the patient usually feels well within a few minutes after recovery. The cause for such syncope is probably pooling of blood in the peripheral vascular bed, particularly in the splanchnic region. This causes a diminished return of the blood to the heart and results in cerebral anoxemia. Such pooling occurs more easily in the upright position, due to the added hydrostatic factor, as a result of decreased "tonus" in the peripheral vascular bed. As Weiss has pointed out, "this instability or loss of tonus may be a permanent constitutional characteristic; it may be the result of prolonged rest in the recumbent position; it may be caused by bacterial toxin or other chemical substances, or it may be a temporary nervous phenomenon of psychic or neurogenic origin."

Such syncope and related symptoms are frequently seen under circumstances where patients stand in one position for a varying period of time, as when soldiers stand at attention or when crowds stand in public gatherings. I am told that

a supply of smelling salts can be found in many beauty parlors for patrons who develop this type of dizziness when they sit with the curling electrodes in place and the head in a fixed upright position. The vasovagal type of dizziness is frequently encountered among patients convalescing from illness when they first assume the upright position. Psychic factors play a varying rôle in initiating or accentuating this syndrome and are the precipitating cause for dizziness or syncope encountered during venepuncture and hypodermic injections, at the sight of blood, in operating room "initiates," and following fright or other emotional reactions. Vasovagal syncope appears to be accentuated by a warm, humid atmosphere.

Treatment consists in correcting any factors which can be shown to contribute to or predispose to such a state. If emotional factors play a rôle, proper psychotherapy should be instituted. The patients should be reassured that such symptoms do not indicate heart disease, as this belief is held by lay people in general. As a rule, subjects who faint at the sight of blood, during injections, etc., can usually overcome this fault through their own efforts. Physical exercise and physical therapy and hydrotherapy are of aid in improving the tonus of the vasomotor system. Abdominal binders in some instances, and proper breathing and postural habits may be of aid. Patients who develop symptoms while standing in one position should form the habit of frequently shifting their weight from one leg to the other. Following prolonged bed rest, elderly patients should particularly be instructed to gradually resume the upright position and warned against standing up too soon. If organic disease is present it should be corrected whenever possible. Dietary deficiencies should likewise be corrected.

The actual attack of syncope or severe dizziness should be treated by first placing the patient in a comfortable horizontal position with the head downward. The clothing should be loosened, particularly about the neck, and cold towels or ice should be applied to the forehead and face. Olfactory stimulants, such as ammonia, seem to be of aid in aborting or shortening the attacks. Massage of the legs and abdomen may be necessary. If unconsciousness is prolonged and other

measures fail, 1 cc. (15 minims) of a 1: 10,000 solution of epinephrine may be given intravenously.

Dizziness and Syncope of Carotid Sinus Origin.—Abnormality of the carotid sinus mechanism has been found to be a not uncommon cause for dizziness and fainting, and detailed discussion of this syndrome by Weiss, Baker, Capps and myself can be found elsewhere.^{9, 10, 11, 13} The carotid sinus is a plexus of nerves located in the arterial wall at the bifurcation of the carotid arteries. Briefly, the attacks are similar in nature to those encountered in other types of syncope. In the mild attacks, dizziness occurs without actual fainting. Pallor and sweating frequently accompany the attacks but may be absent. The relation of the attacks to the orthostatic position is similar to that of vasovagal syncope. The attacks usually last from one half to two minutes. The diagnosis depends upon reproducing the spontaneous attacks by pressure and massage of the carotid sinus, which is located in the neck just below the angle of the jaw. Pressure should never be exerted over both sides simultaneously. The spontaneous attacks may occur without any apparent cause or they may be initiated by turning the head, pressure from masses in the neck, extreme changes in position of the head either side-wise or upward, psychic and emotional upsets, menstruation and the menopause. Digitalis and dietary deficiency have been found to have a sensitizing effect on this mechanism. The syndrome occurs at any age but is more commonly encountered in the higher age groups, in which instances myocardial and vascular diseases play an important rôle. The symptoms may be due to cerebral anoxemia resulting from either a reflex heart block (vagal type) or a reflex depression of the blood pressure (depressor type); or from a direct central reflex in which no change in the heart rate or blood pressure occurs and the cerebral blood flow is normal (cerebral type).

Treatment consists first in correcting any predisposing factors. Accompanying organic disease such as central nervous system syphilis, cervical adenitis, digitalis intoxication, and dietary deficiency should receive specific treatment. When such symptoms occur with the menopause, glandular therapy might be of value. Patients in whom emotional factors predispose to the attacks should receive adequate psychotherapy.

By changing their trend of thought, by moving about, or through the use of other external stimuli such as smelling salts, pain, etc., the patients can frequently delay or abort both the spontaneous and induced attacks. The patient should be advised as regards turning the head and wearing clothes which press against the region of the carotid sinus, if such factors play a rôle in causing the attacks.

In the vagal type of syncope, where the symptoms are due to cardiac slowing or asystole, atropine by mouth in doses of 0.5 mg. ($\frac{1}{120}$ grain) four times a day or ephedrine by mouth in doses of 30 mg. ($\frac{1}{2}$ grain) three times a day will usually prevent the attacks. If the ephedrine causes nervousness or sleeplessness, the addition of 15 mg. ($\frac{1}{4}$ grain) phenolbarbital to each dose will suffice to prevent such symptoms. Ephedrine in the above dosage will prevent the depressor type of attack. The cerebral type does not respond to specific drug therapy. We have had good results in 9 of 11 such patients by surgical denervation of the most sensitive carotid sinus. The indications and technic for this procedure have been recently described by us. The operation should not be advocated except following prolonged observation and after other measures have failed, and only when the symptoms are severe enough to warrant such a major procedure.

Treatment for the acute attack is similar to that for vasovagal syncope: if the heart rate is slow or the blood pressure very low, 1 cc. of a 1: 10,000 solution of epinephrine should be administered intravenously.

Dizziness and Syncope due to Stokes-Adams Attacks of Reflex Origin.—The vagal type of carotid sinus syncope can be classified in this group and makes up by far the largest percentage of patients having transient attacks of reflex heart block. We have reported^{11, 14} other types of reflex heart block in which the reflex was initiated in the eyeball (oculovagal reflex), esophagus, pharynx, larynx and bronchi (vago-vagal reflex) and produced attacks of heart block associated with dizziness and syncope. These attacks could be reproduced by irritation of the sensitive area and could be abolished with atropine.

As with the vagal type of carotid sinus syncope, the daily administration of atropine or ephedrine in the previously men-

tioned dosage will prevent such attacks. Treatment for the acute attack is similar to that for carotid sinus syncope.

Other Types of Syncope.—A comprehensive discussion of these types can be found elsewhere.¹¹ The treatment of such attacks is similar to that described for vasovagal syncope.

SUMMARY

In evaluating such symptoms as vertigo, giddiness and dizziness, it is important to determine whether they represent true vertigo or whether they represent sensations of a syncopal nature. There is a clear distinction between the two groups of sensations and they represent two separate and distinct syndromes, namely, true vertigo and syncopal attacks. The subjective symptoms of vertigo and those of syncope are each characteristic, regardless of the cause.

CLINIC OF DR. JACOB H. SWARTZ

BOSTON

DISEASES OF THE SKIN

IMPETIGO CONTAGIOSA

Definition.—Impetigo contagiosa is a highly contagious condition of the skin caused by a streptococcus or staphylococcus or both.

Clinical Picture.—The primary lesion of impetigo is a vesicle varying in size from pinhead to the size of a quarter. Soon after the appearance of the lesion the vesicle may become pustular. It is usually situated on an inflammatory base. The lesions tend to flatten down with the formation of a crust which is usually the color of honey. The crusts last a few days, then they are thrown off and leave a red stain which fades gradually. The vesicles or pustules may remain discrete or coalesce and form various figures such as the figure of 8, etc., thus making it easily mistakable for ringworm of the skin (*tinea circinata*).

Impetigo can occur wherever there is an abrasion or may arise from insect bites, scratches, wounds, and intentional scratches due to itching. It is most commonly seen on the face and extremities although it may involve any other part of the body as well as the scalp.

Etiology.—Impetigo is much more common in children. It is highly contagious and auto-inoculable. It is spread from the original lesion by scratching and by careless technic in caring for it. The causative agent, as already mentioned above, is either streptococcus or staphylococcus organism or both. Impetigo contagiosa may complicate scabies, pediculosis capitis, or trauma.

Differential Diagnosis.—Impetigo involving the scalp should be differentiated from: (a) seborrhea capitis, (b)

DIFFERENTIAL DIAGNOSIS HAIRY REGIONS

	Impetigo contagiosa.	Seborrhea capitis.	Psoriasis.	Tinea capitis.	Pemphigus.	Favus.
Primary lesion; vesicle, pustule, or bulla.	Present.	Absent.	Absent.	Absent.	Present.	Absent.
Involvement of hair sheath.	Absent.	Absent.	Absent.	Present.	Absent.	Present.
Honey-colored crust.	Present.	Absent.	Absent.	Absent.	Absent.	Absent.
Scutula.	Absent.	Absent.	Absent.	Absent.	Absent.	Present.
Alopecia.	Absent.	May be present.	Usually absent.	Present.	May be present.	Present.
Microscopic examination for fungus.	Negative.	Presence of bottle-shaped yeastlike organism.	Negative.	Positive.	Negative.	Positive.

DIFFERENTIAL DIAGNOSIS NONHAIRY REGIONS

	Impetigo contagiosa.	Tinea circinata.	Bullous erythema multiforme.	Pustular eczema.	Pemphigus.
Primary lesion.	Vesicle, pustule, or bulla.	Pinpoint vesicle or macule.	Vesicle or bulla.	Papule and pustule.	Vesicle.
Honey-colored crust.	Present.	Absent.	Absent.	Usually absent.	Usually absent.
Duration.	Days to weeks.	Days to weeks.	Weeks.	Months to years.	Months to years.
Microscopic examination for fungus.	Negative.	Positive.	Negative.	Negative.	Negative.
Iris lesions.	Absent.	Absent.	May be present.	Absent.	Absent.
Periophthalma.	Absent.	Absent.	May be present.	May be present.	Present.
Mouth involvement.	Absent.	Absent.	Frequently present.	Absent.	May be present.

psoriasis, (c) tinea capitis, (d) pemphigus, (e) favus. Impetigo of the nonhairy regions should be differentiated particularly from: (a) tinea circinata, (b) erythema multiforme, (c) pustular eczema, (d) pemphigus. Impetigo of the bearded region should be differentiated particularly from sycosis vulgaris. (See differential diagnosis charts, p. 1628.)

Treatment.—Before treating a case of impetigo make sure of the contacts, *i. e.*, if there are any others in the family who have the same condition, otherwise the patient will reinfect himself. It is also important to make sure, if possible, whether the playmates have impetigo.

In the treatment of the impetiginous lesions we use the following lotion and salve:

R̄ Zinci oxidi	5ij
Calamini	5j
Phenolis	5ss
Liquor calcis	q.s. ad 5viij
M.		

Sig.—To be applied twice daily, morning and night.

R̄ Acidi salicylici	5ss
Sulphuris præcipitatis	5ss
Petrolati	5j
M.		

Sig.—To be applied five minutes after using the lotion morning and night.

In those cases where only crusted lesions are present and in hairy regions the lotion is omitted and the ointment alone is used.

We advise against forcible removal of crusts. The parts involved should be washed with boric acid solution, using a separate piece of cheesecloth or cotton pad for each involved area. Wherever possible the lesions should be kept covered, especially in the case of a child. In the very extensive cases the use of ultraviolet rays aiming for an erythema dose in conjunction with the above-mentioned treatment is very helpful.

In cases of impetigo of the face or scalp be sure to examine for pediculosis capitis. If this condition is present treat as follows: pour 1 pint of carbolic acid (1: 20) into a pitcher and add to it 1 pint of hot water, or use 1 tablespoonful of

95 per cent carbolic acid to 1 quart of hot water; tie a towel over the patient's eyes, place the patient's head over the basin and pour the carbolic acid solution (1: 40) over the hair; catch the solution in a basin and pour it back into the pitcher. Repeat the process until the hair is thoroughly soaked. Allow the hair to drip over the basin for a few seconds and then tie up the patient's head in a towel for one hour. To remove the nits which have been killed by the carbolic acid the hair should be combed, preferably with a wired comb known as a Derbac comb.

If the above method is not practicable in some instances, the following procedure may be used: the application of the following ointment nightly, followed by shampoo and fine combing in the morning. This is done until all evidence of nits has disappeared.

R̄ Acidi salicylici	5ss
Sulphuris praecipitatis	5ss
Petrolati	5j
M.	

Be sure to rule out scabies as an underlying cause. If present, treat it.

IMPETIGO CONTAGIOSA OF THE NEWBORN

Definition.—This is a highly contagious skin condition appearing within the first few days of life and is caused by a streptococcus organism.

Clinical Picture.—The primary lesion is a vesicle or bulla, varying in size and number. These rupture easily, leaving bright red, moist, denuded areas. The chief location is in the folds of the axillae and groins, but may occur all over the trunk. This is a serious infection in the newborn.

Treatment.—If there are many areas and the body is extensively denuded, the child should be completely undressed and placed under a cradle that is heated by electric light bulbs. The bullae are cautiously ruptured, being careful not to allow the serum to run down to the normal skin by using a sterile cotton ball to collect the serum. Use a fresh cotton ball for each lesion. This is followed with the application of the following lotion:

R Zinci oxidi	ʒij
Calamini	ʒj
Phenolis	ʒss
Liquor calcis	q.s. ad ʒviij
M.	

Gentian violet (1 per cent aqueous solution) may be used in place of the above lotion.

Precautions.—1. Isolate the child at the first sign of a lesion.

2. Boil all equipment that is boilable. Discard and burn all other material.

3. The nurse should wear a gown when in contact with the patient. Hands should be thoroughly washed after handling patient.

4. In the case of breast-fed infants, it is advisable to pump the mother's breasts and feed the baby from a bottle.

ALOPECIA AREATA

Definition.—Alopecia areata is a disease of the scalp characterized by the presence of sharply defined patches of partial or complete baldness.

Clinical Picture.—The bald patches vary in size and configuration, and may be discrete or confluent. The skin is shiny and smooth, but not atrophic. Exclamation point hairs are found, particularly at the advancing border. The extent of involvement varies from one small patch to involvement of practically the entire scalp area.

In adult males the condition may be present over the bearded region.

Alopecia areata may become universal, involving the eyebrows, eyelashes, the axillary and pubic regions, as well as the rest of the trunk.

Etiology.—Cause unknown. *Theories:* (1) trophoneurotic; (2) endocrine disturbance; (3) parasitic; (4) dietary.

The trophoneurotic theory is based on the fact that cases have been reported following shock, anxiety, or worry. In rare cases the patches of alopecia follow a nerve area.

The endocrine theory is based on some good results obtained with the administration of thyroid.

The parasitic theory is based upon reported epidemics in institutions.

The diet deficiency theory is based upon cases reported improved when put on a high cystine diet.

Alopecia areata must be differentiated chiefly from luetic alopecia. (See chart below).

	Alopecia areata.	Luetic alopecia.
Circumscribed patches of baldness.	Present.	Absent.
Moth-eaten appearance.	Absent.	Present.
Exclamation point hairs.	Present.	Absent.
Other manifestations of lues.	Absent.	Usually present.
Serology.	Negative.	Positive.

Treatment.—1. Complete physical examination to rule out foci of infection. If present it is wise to eliminate them if possible.

2. Glandular therapy, thyroid or pituitary.

3. Sulphur treatment—taken either internally in the form of 5 grain tablets three times a day or collodial sulphur injections. Caution—watch for mucous colitis.

4. High cystine diet.

5. Local treatment is used with the purpose of producing local stimulation and hyperaemia.

(a) Potassium permanganate, 1 per cent, painted on morning and night.

(b) The following ointments may be used in place of the potassium permanganate:

℞ Acidi salicylici	
Sulphuris praecipitatis	āā ʒss
Petrolati	ʒj
M.	

Sig.—Applied nightly.

℞ Phenolis	
Sulphuris sublimatis	āā ʒj
Naphtholis	ʒss
Cerae albae	ʒijj
Adipis	ʒv
M.	

(c) The Kromayer lamp to the affected parts, aiming for an erythema or vesiculation, and the air cooled lamp to the

trunk, aiming for a tonic dose. The general treatment is given about twice a week, while the treatment with the Kromayer lamp is repeated when the effects of the last treatment have disappeared.

FUNGUS DISEASES OF THE SKIN

A fungus is a vegetable parasite which, if pathogenic, can attack skin, its appendages, such as hair and nails, mucous membrane, or the viscera. In this article a discussion of its pathogenicity as far as the skin and its appendages is in place.

Classification of Fungi.—Only a classification which can be applied to the clinical conditions to be discussed will be attempted. A strict botanical classification is too confusing and at present not most practical.

Group I. The myxomycetes.

Group II. Eumycetes.

The fungi pathogenic to man usually belong to Group II, which may be further subdivided as follows:

1. Phycomycetes. Reproduction by zygospores. Mycelium usually nonseptate and multinucleate.

2. Basidiomycetes. Reproduction by means of basidiospores. Mycelium septate.

3. Ascomycetes. Reproduction by means of ascospores. Mycelium is septate when present.

4. Hyphomycetes (Fungi imperfecti). Reproduction is by free borne spores (conidia). Ascus body absent. Mycelium septate. Complete sexual reproduction absent or unknown.

Fungi pathogenic to man belong chiefly to groups 3 and 4. For the sake of convenience to the clinician the above two groups may be further classified as follows:

(a) Yeasts and yeastlike organisms.

1. Saccharomycetaceae (true yeasts).

2. Cryptococcus (Torula).

3. Monilia.

4. Endomyces.

5. Coccidioidaceae.

(b) Ringworm fungi (Gymnoascaceae).

1. Microsporon

lanosum.

audouinii.

2. Achorion

quinckeanum.

schönleini.

3. Trichophyton

Ectotrichophyton, *e. g.*, *T. gypseum*.Megatrichophyton, *e. g.*, *T. rosaceum*.Favotrichophyton, *e. g.*, *T. ochraceum*;
T. violaceum.

Eutrichophyton,

Neoendothrix, *e. g.*, *T. cerebriform*.Endothrix, *e. g.*, *T. crateriforme*; *T. acuminatum*.

4. Epidermophyton

The organisms which cause sporotrichosis and actinomycosis belong to the Fungi imperfecti.

Diagnosis.—In addition to the clinical characteristics laboratory data is essential for the correct diagnosis of fungus infection. The simplest method is the *direct microscopic examination* of the material suspected.

Technic.—1. Select the proper material for examination, since many negative findings are due to selecting the material in a hit or miss manner. In tinea capitis or favus select the stumps of hairs; in tinea barbae examine the hairs in pustules or nodules as well as the seropurulent material; in blastomycosis and sporotrichosis examine the fluid in the nodules and abscesses; in tinea of the glabrous skin such as tinea circinata, tinea cruris epidermomycosis of the hands or feet, the skin scales from the roofs of fresh vesicles are to be taken for examination.

2. Place some of the material between two slides which can be held together by elastic bands, label and put away for cultural purposes. The remaining material is used for microscopic examination.

(a) Unstained preparation: place the scales on a slide and add a few drops of potassium or sodium hydroxide (30–40 per cent). Put on cover slip and heat gently. Allow it to stand for ten to fifteen minutes for clearing and then examine with microscope.

(b) Stained preparation: place the scale on a slide and add a few drops of 5–10 per cent of potassium hydroxide and heat slightly. Wash scale in water for two to three minutes, using a watch crystal. Put scale back on slide and add a drop of ½ per cent lactophenol cotton blue, put on cover glass and heat slightly. In case of thick scales or nail preparation a 1 per cent alcoholic solution of cotton blue is used and the preparation is mounted in clear lactophenol.

TINEA CAPITIS (RINGWORM OF THE SCALP)

This is a disease of the scalp caused by different species of vegetable parasites. It is a disease of childhood chiefly and is highly contagious.

Clinical Picture.—The following are the most characteristic findings: (1) scaliness; (2) broken off hairs covered with a grayish sheath; (3) prominent hair follicles; (4) partial baldness; (5) in some instances the follicular openings stand out as large black dots.

All or part of the above findings may be noted. The patches may be discrete and scattered, varying in size, or they may coalesce to involve almost the entire scalp. Involvement of adjacent nonhairy skin may be noted, particularly when the offending organism is of the large spore variety.

Etiology.—The condition is most common in children under puberty, although scattered reports of occurrences in adults are present. The causative agent is a vegetable parasite either of the large or small spore variety. In this part of the country the *microsporon lanosum* is the more common offending agent.

Sources of Infection.—(1) Pet animal, (2) contact with infected child, (3) interchanging of caps, and (4) combs and brushes.

DIFFERENTIAL DIAGNOSIS

	Tinea capitis.	Impetigo.	Seborrhea capitis.	Favus.	Psoriasis.
Broken off hairs covered with a grayish sheath.	Present.	Absent.	Absent.	Absent.	Absent.
Silvery scale.	Absent.	Absent.	Absent.	Absent.	Present.
Scutula.	Absent.	Absent.	Absent.	Present.	Absent.
Atrophy	Absent.	Absent.	Absent.	Present.	Absent.
Honey-colored crusts on nonhairy regions	Absent.	Present.	Absent.	Absent.	Absent.
Greasy yellowish scale.	Absent.	Absent.	Present.	Absent.	Absent.
Age of incidence	Under puberty.	Usually children.	All ages but more common in adults.	All ages.	Usually young adults.
Microscopic examination for fungus	Positive	Negative.	Negative.	Positive.	Negative.

KERION

This is a purulent type of lesion simulating a large abscess or carbuncle and most often seen in children.

Clinical Picture.—(1) Partial alopecia; (2) inflammation; (3) edema and bogginess; (4) a carbuncle-like tumor which discharges a mucoid or mucopurulent secretion.

Pain may or may not be present. Microscopic examination of the secretion or the involved hairs shows the presence of a large spored ringworm. Caution: this condition must not be mistaken for boils or carbuncles, because incision may cause a spread of the disease.

Treatment.—The disease responds well to treatment, which consists of a daily shampoo of soap and water, followed by the application of a mild fungicidal ointment such as

R	Acidi salicylici	5ss
	Sulphuris præcipitatis	5ss
	Petrolati	5j
	M.	

The child should not be allowed to attend school until the condition is cured. Boilable caps must be worn. (See *Tinea Capitis*).

TINEA FAVOSA

This disease is caused by a vegetable parasite known as *Achorion schönleinii* and may involve the skin, nails, or scalp, particularly the last.

Clinical Picture.—The following characteristics are usually found in favus involving the scalp. (1) Scutula. These are yellow cup-shaped crusts which are more commonly found at the periphery of the involved areas and resemble small mushrooms. (2) Brittleness and loss of hair. (3) Atrophy and loss of hair. (4) Offensive odor which may be compared with that of the urine of mice.

Differential Diagnosis.—See *tinea capitis*.

Etiology.—This disease is caused by a vegetable parasite known as the *Achorion schönleinii*. It attacks both sexes and may occur at any age.

Modes of Transmission.—(1) Direct contact with an individual afflicted with the disease; (2) pet animal, particularly cat; (3) contaminated articles, particularly cap, brush or comb.

Treatment of Tinea Capitis and Tinea Favosa.—Since the infection involves the hair, the logical procedure is to get

rid of the infected hairs by one of the following procedures: (a) manual epilation; (b) x-ray epilation, or (c) epilation with thalium acetate.

Manual epilation can be accomplished by plucking out the infected hairs by means of an epilating forceps, or by stripping the affected areas after the application of adhesive plaster. It is advisable to cut the hairs short or even shave them in order to find the exact extent of the involvement. The manual epilation should be done daily in order to be effective. The infected hairs which have been removed should be collected in a paper bag and then burned. Following the epilation an application of the following lotion should be made on two successive days and the ointment on the third day:

℞ Phenolis	
Camphorae	āā 5j
Iodine	5j
M.	

℞ Acidi salicylici	
Sulphuris praecipitatis	āā 3ss
Petrolati	5j
M.	

The following ointment may be used daily instead of the above combination:

℞ Sulphuris sublimati	5j
Phenolis	5j
Naphtholis	3ss
Cerae albae	5iij
Adipis	5v
M.	

Ethyl Iodide Inhalation.—This method of treatment was originated by Swartz, Blumgart, and Altschule and is as follows: by means of a special inhalation apparatus ethyl iodide is inhaled on two successive days and omitted on the third day. The dose begins with 1½ cc. (3 Gm.) and is increased ½ cc. (1 Gm.) per dose until 4 cc. (8 Gm.) is reached. The dose for children is one half of the above mentioned. (For further information see treatment of epidermophytosis).

x-Ray Epilation.—This method of treatment is risky except in the hands of experts since the margin of safety is narrow and permanent epilation may result (for technic see

McKee's book on "x-Ray Treatment of the Skin" or other standard textbooks on dermatology). Caution: no irritating or stimulating ointments should be used for at least ten days prior to x-ray treatment and for two weeks after the treatment.

Thallium Acetate.—This drug is known to cause a temporary epilation but is rather dangerous in the hands of the inexperienced, as it has been known to produce fatalities. Its action is chiefly on the sympathetic nervous system. The dosage is 8 mg. per kilogram of body weight and it is dissolved in sweetened water made up as follows: 1 teaspoonful of sugar to 100 cc. of water. The treatment should not be repeated within three months. The first signs of epilation are usually noticed two weeks after the administration of the drug. The local treatment is the same as above.

Prophylaxis.—(1) If pet animal is found to be the causative agent it should be sent to an animal hospital for treatment or disposal; (2) epilated infected hairs must be collected in paper bag and burned; (3) sterilize by boiling the clippers and other utensils after using; (4) wear boilable stocking caps. These should be boiled for twenty minutes after using; (5) all outside caps that have been worn should be burned; (6) the child should not be allowed to attend school until three successive negative weekly microscopic examinations have been obtained.

TINEA BARBAE (TINEA SYCOSIS; RINGWORM OF THE BEARD)

Definition.—This disease is an infection of the hairs in the bearded region caused by a vegetable parasite, chiefly of the large spore variety.

DIFFERENTIAL DIAGNOSIS

	Tinea barbae.	Sycosis vulgaris.
Distribution.	Common in the mandibular and submaxillary regions, rarely on the upper lip.	Beard and upper lip.
Primary lesion.	Nodule with tendency to abscess formation.	Follicular pustule or papule.
Microscopic examination for fungus.	Positive.	Negative.

Clinical Picture.—The chief characteristics are: (1) hairs that are loose and broken off; (2) partial alopecia; (3) nodular abscesses resembling kerion; (4) location is chiefly mandibular or submaxillary regions; practically never involves the upper lip. The condition is rather rare.

Treatment.—(1) *Epilation.*—(a) Manual epilation in conjunction with local application as in tinea capitis; (b) x-ray epilation (for technic refer to McKee's textbook on "x-Ray Treatment of the Skin" or Andrew's book on Dermatology); the x-ray treatments have also beneficial action upon the accompanying inflammatory tissue.

(2) *Shaving Precautions.*—(a) Omit shaving brush as it cannot be sterilized by boiling; (b) new blade for each shave; (c) sterilize blade holder by boiling or by keeping in alcohol overnight; (d) do not shave too close; (e) shave uninvolved areas first and leave involved areas for last. The electric shaver has been found to be less irritating than the average razor.

TINEA CIRCINATA

Tinea circinata is a highly contagious disease of the glabrous skin characterized by the presence of circinate erythematous lesions with a border made up of minute vesicles. The disease is more common in children.

DIFFERENTIAL DIAGNOSIS

	Tinea circinata.	Impetigo contagiosa.	Syphilis.	Eczema.
Sharply defined border	Present.	May be present.	May be present.	Usually absent.
Circinate lesions.	Present.	May be present.	May be present.	Usually absent.
Vesiculation at border	Present.	May be present.	Absent.	May be present.
Clearing center	Present.	May be present.	May be present.	Usually absent.
History of contagion	Present.	Present.	Present in early stages.	Absent.
Honey-colored crust	Absent.	Present.	Absent.	Absent except in impetiginous eczema.
Serology	Negative.	Negative.	Positive.	Negative.
Microscopic examination for fungus	Positive.	Negative.	Negative.	Negative.

Clinical Picture.—This disease presents the following characteristics: (1) circinate erythematous lesions

varying in size. Some of the lesions may even resemble the figure 8 or form a circle within a circle; (2) a border consisting of minute vesicles and crusting; (3) tendency toward clearing in the center; (4) absence of atrophy or scarring; (5) usually found on the face or neck, but may be found on any part of the trunk or extremities.

Modes of Transmission.—(1) Direct contact with individual that has the disease; (2) pet animal (cat or dog); (3) contaminated clothing, etc.

Treatment.—Since the condition is contagious, the child should not be allowed to attend school. Be sure to locate, if possible, the source of infection.

Locally the lesions are washed separately, using a separate piece of gauze for each area, and a fungicidal ointment such as listed below is applied morning and night. The disease responds readily to treatment.

℞ Acidi salicylici	
Sulphuris praecipitatis	āā 5ss
Petrolati	5j
M.	

CRYPTOCOCCOSIS EPIDERMICA

This condition was described by Dr. C. J. White and Dr. J. H. Swartz in 1928. The disease affects the female sex largely, may appear at any age and last indefinitely if untreated. It usually begins on the eyelids, particularly the upper, and may spread to the flexures of the elbows, thighs and popliteal spaces. The lesions are polymorphous, chiefly macular and infiltrative, but never moist unless secondarily infected with bacteria. In the early stages the lesions have a café-au-lait color, but later may become lichenified and even pigmented. The organism found on direct microscopic examination of the scales is a budding yeast of the cryptococcus family. The chief symptom is itching, at times severe.

Treatment.—(1) Clothes that can be washed and boiled should be worn next to the skin; (2) a superfatted soap for bathing purposes; (3) the following ointment should be applied one or two times daily to all involved parts except eyelids:

R Mercurochrome crystals	gr. x
Aquae	℥ xx
Acidi salicylici	ʒss
Petrolati	
Lanolini āā	q.s. ad ʒj
M.	

(4) In some cases fractional doses of x-ray is helpful. The following ointment is advised in conjunction with the x-ray treatment:

R Mentholis ..	gr. $\frac{1}{4}$ -1
Zinci oxidi	ʒss
Amyli	ʒij
Petrolati ..	ʒj
M.	

(5) Ethyl iodide inhalation. This is used in the more extensive cases. (See epidermophytosis.)

EPIDERMOPHYTOSIS (DERMATOMYCOSIS, ECZEMA MYCOTICUM)

This condition is caused by a variety of vegetable parasites and resulting in various clinical pictures dependent upon the location. Four types are particularly known, although others have been described.

Clinical Types.—1. The *erythematous*—more commonly found in the folds such as the groins, perineum, axillae, and under the breast in females. The lesions are usually sharply demarcated with maceration in the fold and a slightly elevated border, frequently made up of pinpoint vesicles. In long-standing cases one may also note lichenification and pigmentation; the latter is particularly present in brunettes and in those with tendency to pigment.

2. The *vesicular type* occurs chiefly on the palms, plantar aspects, and interdigital spaces. The vesicles are intradermal, resembling sago grains, and when drying up turn brownish in color. Occasionally one may even note bullae. Secondary infection with resulting pustulation is not uncommon. In addition, there is scaling, maceration, crusting and fissuring. Lymphangitis and lymphadenitis may accompany this condition, especially when the infection involves the feet.

3. *Hyperkeratotic Type*.—Epidermophytosis is inclined to hypertrophy in regions in which the stratum corneum is nor-

mally abundant. On the palms hyperkeratosis is relatively mild but common; on the soles it is decidedly emphasized and still more frequent. The color of the lesions is usually yellow or more often a striking orange. The more common locations are the inner side of the big toe, the ball of the foot and the heel. Fissuring frequently accompanies this condition.

4. The *macerated form* has its predilection in the webs of the fingers and of the toes, the intergluteal fold, the contact points of the penis and scrotum, and the submammary folds. This form occurs particularly in association with the above described erythematous type, especially in the folds of the skin.

5. The combination of any of the above four types with one type predominating is not infrequently seen.

Treatment.—The results in the treatment of epidermophytosis at best is not most satisfactory but with the patient's cooperation and a definite understanding of the pathology by the physician, one can frequently obtain gratifying results.

The following are some of the fungicidal preparations used: chrysarobin, iodine, thymol, oil of cinnamon, potassium permanganate, copper sulphate, gentian violet, mercurochrome, sodium hyposulphite, sulphur, benzoic acid and salicylic acid. A keratolytic agent is necessary in combination with the fungicidal preparation in order to obtain results. Salicylic acid in strengths from 3 to 6 per cent is most frequently used.

The following are some of the fungicidal ointments advised:

R Iodine crystals	gr. v-x
KI enough to dissolve the iodine	
Acidi salicylici	ʒss
Lanolini	
Petrolati āā	q.s. ad ʒj
M.	

The iodine and its solvent may be omitted or it may be replaced by 1 per cent thymol or 3 per cent chrysarobin.

R Acidi salicylici	gr. xv
Acidi benzoici	gr. xxv
Paraffini mollis	ʒij
Olei cocois nuciferae	q.s. ad ʒj
M.	

R Mercurochrome crystals	gr. x-xx
Aquae	m xx
Acidi salicylici	5ss
Petrolati	
Lanolini āā	q.s. ad 3j
M.	

Particularly useful in the vesicular type.

In all instances it is wise to precede the application of the ointment by a soaking of the hands or feet in warm saturated solution of boric acid or potassium permanganate, $\frac{1}{20}$ to 1 per cent solution.

In the severe cases the soaks and applications are made morning and night. In order to protect the bed linen the patient is advised to wear old cotton stockings on the feet (use a woman's stocking, cut out the heel and cut down the leg part to make two ties and fasten about the ankle to hold the dressing in position). The patient should also wear cotton gloves on the hands. In the milder types, the patient is told to soak the affected parts morning and night, but the ointment is applied only at night. In the morning he is to dust a powder between the toes. Boilable socks must be worn.

The following powder is useful as a prophylaxis in epidermophytosis of the feet:

R Acidi salicylici	2
Acidi benzoici	2
Talc	30

Caution: beware overstimulating and strong applications in the acute stages. It will only serve to aggravate and spread the condition.

Treatment of Shoes.—Soak paper towels in formalin, being careful to protect the hands; stuff the soaked papers into the shoes and slippers. Place in a large paper bag, tie with a string and put into the closet for twelve hours. Remove the paper and place the shoes and slippers out in the sun for at least twenty-four hours to air before wearing them.

Ethyl Iodide Inhalations.—In the acute vesicular cases, in the cases with an accompanying epidermophytide or trichophytide, and in stubborn cases of long standing, the administration of ethyl iodide by means of inhalation is advised.

Technic.—The inhaler devised by Swartz, Blumgart, and

Altschule is used. This inhaler is so devised that a comfortable mixture of ethyl iodide and air is inhaled by the patient. Dosage: begin with $1\frac{1}{2}$ cc. (3 Gm.) of ethyl iodide and increase $\frac{1}{2}$ cc. (1 Gm.) per dose until a total of 4 cc. (8 Gm.) is reached. Continue with 4 cc. Inhalations are given on two successive days and omitted on the third day until marked improvement is noted, when the treatment is administered less and less frequently.

Caution: (1) Do not administer ethyl iodide to patients suffering from pulmonary tuberculosis or nephritis; (2) watch for an iodide rash. If present, omit treatment till eruption disappears and then start gradually; (3) watch for peripheral neuritis. This is a rare complication. If noted, omit treatment and do not attempt inhalations again.

Prophylaxis.—The rules to be observed are: (1) Do not walk around with bare feet; (2) do not wear anyone's slippers or shoes; (3) wear rubber slippers or place a towel on the shower-bath floor; (4) wash feet at least once a day with soap and water. Dry thoroughly but gently; (5) apply powder mentioned in the discussion of treatment; (6) treat shoes as advised in discussion of treatment if there is any question of contamination.

The treatment with trichophytin injections has not proved most successful in the author's hands. However, the development of autogenous vaccines might prove to be valuable.

EPIDERMOPHYTIDE OR TRICHOPHYTIDE

In addition to the direct infection one may see a toxic or allergic eruption which is symmetrical and which is commonly seen on the extremities, particularly the upper, and may be macular, papular, or vesicular in character. It may also be follicular, lichenified, or squamous. On microscopic examination one never finds the fungus in the skin scrapings from these lesions.

EROSIO INTERDIGITALIS

This condition is more frequently seen in housewives and dishwashers. It is caused by a yeastlike organism belonging to the monilia family. The infection usually attacks the cleft of the middle and ring fingers or that of the middle and fore-

fingers of one or both hands; sometimes, though not often, two interspaces of one hand may be involved. The affected area is dirty white, soft from edema, sharply defined, and the border is frequently red and angry.

Treatment.—1. Hands must be protected from the dish water either by wearing white cotton gloves and thin rubber gloves over them or by washing dishes in such a way as to avoid getting the dish water on the hands.

2. *Local treatment:*

℞ Mercurochrome crystals	gr. x
Aquae	℥ xx
Acidi salicylici	℥ss
Petrolati	
Lanolini āā	q.s. ad 5j
M.	

Sig.—To be applied morning and night.

Cleanse the involved areas with a saturated solution of boric acid.

℞ Mild mercurous chlorid	gr. xxx
Lime water	q.s. ad 5viij
M.	

Apply with gauze moistened in this solution and allow it to stay in each involved area for five to ten minutes. Do this about three times daily.

Between the applications a drying antiseptic powder should be dusted on frequently.

TINEA VERSICOLOR

Definition.—An eruption of the skin involving particularly the upper trunk and caused by a vegetable parasite known as the *microsporon furfur*.

Clinical Picture.—The lesions are macular in type, varying in size from pinhead to large patches when coalescence takes place. The color varies from the most delicate buff to a reddish deep brown, or even blackish hue. The macules are covered with a furfuraceous scale which on direct microscopic examination reveals the presence of spores and hyphae. The upper trunk is chiefly involved but it may extend to axillae, abdomen, and groins.

Etiology.—The disease is caused by a vegetable parasite known as the *microsporon furfur* and first described by Eichstedt in 1846. It is not easily transmitted but members of one family have been known to communicate the disease occasionally to one another. This organism which is so easily

demonstrated on direct microscopic examination of the skin scales has not been successfully cultivated.

Treatment.—1. Daily hot bath followed by the application of sodium hyposulphite (25 per cent solution) or the following ointment:

R̄ Acidi salicylici	
Sulphuris praecipitatis	āā 3ss
Petrolati	3j
M.	

2. Ultraviolet light aiming for erythema doses.

No matter what type of treatment is used, care must be taken to boil the underclothing or wash and press with a hot iron.

BLASTOMYCOSIS

Blastomycosis may be either primary or secondary to some deeper infection of the viscera or bony structure. Only primary blastomycosis will be discussed here.

Clinical Picture.—Cutaneous blastomycosis is known to produce granulomatous lesions which progress slowly and are warty in character and show multiple discharging sinuses. The lesions are often multiple and are most frequently seen on exposed parts, although they may occur on any part of the integument. The lesions when present on the hands and feet show a greater tendency to papillomatous formation. The lesions are usually covered with a thick dirty gray or brown crust which, on removal, shows exuberant granulations covered with seropurulent exudate. The discharge is found to come from multiple sinuses which communicate with multiple subcutaneous abscesses. The lesions show a tendency to central involution with scar formation. Frequently the lesions simulate tuberculosis verrucosa cutis and can only be differentiated from it by histological and mycological studies.

Etiology.—The family of organisms causing blastomycosis belong in the yeastlike family and fungi imperfecti. The belief that one individual organism is responsible for all cases of blastomycosis is not accepted by most mycologists. It is generally accepted that there are a plurality of species of the fungi causing this disease.

Treatment.—(1) Surgery or surgical diathermy; (2)

x-ray treatment; (3) massive doses of iodides by mouth, intravenously, or by inhalation of ethyl iodide; (4) a combination of any or all of the above methods.

SPOROTRICHOSIS

Definition.—Sporotrichosis of the skin is a subacute or chronic infectious disease due to one of several species of vegetable parasites of the genus *sporotrichum* and characterized by the presence of subcutaneous nodules which tend to follow lymphatic distribution. This variety is the most common in America. Other varieties have been described, but because of the rarity, will not be considered here.

Clinical Picture of Lymphangitic Sporotrichosis.—The primary sore which is a nodule or ulcer usually follows trauma and appears at the point of inoculation. The lesions that follow are multiple subcutaneous painless nodules which soften and break down. An ascending lymphangitis may accompany the nodules. This is characterized by a painless, cordlike thickening of the lymphatic vessels.

Treatment.—Iodine is the drug of choice given orally, intravenously or by inhalation (ethyl iodide). Some recommend x-ray therapy either alone or in conjunction with iodides. Iodine ointment to the lesions is helpful. Surgery is contra-indicated.

CHRONIC PARONYCHIA

Definition.—Chronic paronychia is an infection of the nail and surrounding soft tissue caused by a pathogenic yeast, usually a monilia.

Clinical Picture.—The outstanding characteristics are: (1) A thickening and inflammation of the soft tissue about the nail; (2) grooving and partial destruction of the nail, particularly at the lateral border and at the base. Any nail may be involved. In association with this condition one frequently finds an *erosio interdigitalis* (described above). Both conditions are found particularly in domestic servants, housewives, and dish washers. The starting point is probably trauma from the excessive use of warm water. This is later followed by a superimposed yeast infection from contact with fruits, vegetables and dish water. The cocci may produce a

picture simulating the one just described, and might necessitate laboratory studies to differentiate.

Treatment.—(Same as for Erosio Interdigitalis).

ONYCHOMYCOSIS (TINEA UNGUIUM, RINGWORM OF THE NAIL)

Definition.—Onychomycosis is an infection of the nail caused by a vegetable parasite.

Clinical Picture.—The involved nail is brittle, discolored yellowish brown or darker, lusterless and hypertrophic. One or all of the nails of the hands and feet may be involved. It may accompany fungus infection of the skin or it may be the sole finding. The nail bed and the lateral aspects of the finger nails are chiefly involved. Beneath the involved parts, particularly the lateral margins, are accumulations of soft débris. Involvement of the soft tissue about the nails may or may not be present. The condition is rather persistent and resistant to treatment.

DIFFERENTIAL DIAGNOSIS

	Onycho- mycosis.	Lues.	Psoriasis.	Dystrophy.
Pitting and stippling.	Absent.	Absent.	Present.	Absent.
Yellowish-brown discoloration.	Present.	Absent.	May be present.	Absent.
Other psoriatic lesions.	Absent.	Absent.	Usually present.	Absent.
Other manifestations of lues.	Absent.	Usually present.	Absent.	Absent.
Other manifestations of trophic disturbances.	Absent.	Absent.	Absent.	Usually present.
Serology.	Negative.	Positive.	Negative.	Negative.
Microscopic examination for fungus.	Positive.	Negative.	Negative.	Negative.

Treatment.—(1) *Local Treatment.*—(a) Warm boric acid solution soaks for fifteen minutes twice daily; (b) scrape the involved nails with the rough side of a broken slide or with a knife until it hurts; (c) apply one of the following ointments:

R Acidi salicylici
Acidi benzoici
Adipis
M

℥ss
ʒj
ʒj

R̄	Mercurochrome crystals	gr. x
	Aquae	℥ xx
	Acidi salicylici	℥ss
	Lanolini	
	Petrolati āā	q.s. ad 5j
	M.	

Sodium perborate paste may be used in place of the above salves. A few drops of water are added to sodium perborate powder to make a paste. This is applied to the fingernail and nail bed and covered with a rubber finger cot and allowed to stay on overnight. It is helpful to soak the nails in a warm saturated solution of boric acid before applying the paste.

2. x-Ray treatment.

3. Surgery in combination with above mentioned local treatment.

4. Ethyl iodide inhalations.

ERYTHRASMA

This condition is not common in temperate climates but it is seen often enough to merit some consideration. It is characterized by brownish, slightly scaly, fairly demarcated superficial patches involving chiefly the axillae and groins. It is only mildly infectious, and is caused by a *Microsporon minutissimum* which can be demonstrated by direct microscopic examination of the scales.

Treatment.—Sodium hyposulphite, 25 per cent solution, applied nightly until all signs of the condition disappear or

R̄	Acidi salicylici	
	Sulphuris praecipitatis	āā 5ss
	Petrolati	5j
	M.	

SIG.—Apply nightly until all signs of activity have disappeared.

CLINIC OF DR. CHESTER M. JONES

MASSACHUSETTS GENERAL HOSPITAL

THE TREATMENT OF JAUNDICE AND HEPATIC INSUFFICIENCY

THE success of medical treatment of disease of the liver depends in large part upon a proper understanding of the physiological significance of hepatic insufficiency. Few of the many functions of the liver are accurately understood, but there is a sufficient amount of information regarding them to enable one to obtain a fairly clear clinical understanding of the processes involved in hepatic failure. Regardless of the type of liver disease, whether it be due to acute infection or to a specific toxin, the problem is always one of a restoration of certain specific phases of liver function. Of these the best understood is that related to sugar metabolism and glycogen deposition. Next in importance is the detoxification of various poisonous substances, bacterial or otherwise, deaminization of amino acids, the maintenance of serum protein, particularly through the formation of fibrinogen, the control of normal blood coagulation, participation in the formation of hemoglobin, the control of body fluids through an adequate portal circulation and maintenance of serum protein, the excretion of bile and the formation of bile acids, and the elimination of foreign substances. When these functions are disturbed certain symptoms may appear which properly may be ascribed to these various phases of hepatic insufficiency. Improper handling of carbohydrate probably accounts for the marked weakness and occasional fainting attacks in acute liver disease. The anemia is undoubtedly the result of the failure of the liver to aid in the formation of hemoglobin and in the maturation of red cells as well as to the presence of spontaneous hemorrhages from mucous membranes. The occur-

rence of edema and ascites in association with oliguria obviously is due to a breakdown in the normal control of body fluids in their relation to serum protein, liver glycogen, and portal flow. Jaundice results from the inability of the liver to excrete bilirubin and the lack of proper fat absorption from the digestive tract is intimately associated with the inadequate supply of bile acids to the bowel. Failure of the liver to excrete foreign substances at least provides an opportunity for measuring one of the liver functions, namely, the ability of the liver to excrete dye such as bromsulphalein or rose bengal and permits us to measure liver efficiency to a certain extent. The toxemia that is so frequently present in severe liver disease may be due to a combination of many of the above factors and may be associated with such varying symptoms as drowsiness, nausea, vomiting, and purpura. Acidosis may occur either in the form of a ketosis due to starvation or because of an excessive amount of amino acids in the blood with a resulting diminution of the normal alkali reserve.

If one is to treat the symptoms enumerated above and to attempt to restore to a normal level the hepatic functions which they represent to a greater or lesser extent, one must employ certain specific measures. These are, in the order of importance, complete rest, removal of any specific poison such as alcohol, cinchophen, etc., an adequate supply of simple carbohydrate and a minimal amount of fat, moderate limitation of fluid intake, a diet that contains at least a maintenance ration of protein, transfusion as needed to combat anemia and spontaneous hemorrhage, aided by adequate amounts of iron, diuretics, and possibly alkali at times to combat an existing acidosis. The principles of such treatment have been more or less generally recognized for some years, but failure to successfully treat individual cases of severe liver disease may frequently be laid to the fact that the treatment did not include a sufficient consideration of all the above factors. It is true, however, that in the past few years cases which were given up as hopeless frequently have been successfully treated with a resulting restoration of almost normal function.

The following cases are presented in brief detail as examples of adequate and successful treatment in patients suffering from serious hepatic failure.

The first case is that of an emotionally unstable woman of thirty-nine who had had no symptoms prior to five years before admission to the hospital. At the beginning of this period she began to consume gradually increasing amounts of alcohol, finally taking about $\frac{1}{2}$ pint daily. She was habitually constipated until two years before admission at which time her bowel movements became more regular and less constipated. She had had an increasing number of digestive symptoms during this period consisting of anorexia, gas, nausea and finally vomiting. These symptoms had all increased strikingly in the year preceding admission to the hospital. Eight months before admission she noticed that her clothes were apparently too tight, as if her abdomen were becoming larger. Five months later the patient's sister noticed that her eyes were becoming yellow and associated with this there was noticeable swelling of the feet without fatigue, dyspnea, cardiac, or urinary symptoms. There was no abdominal pain at any time. During the few weeks before admission her bowel movements had become light in color. In spite of the apparent increase in the size of her abdomen she had lost 36 pounds in the last year of her present illness. Just prior to admission she consulted a doctor who told her she had a slight elevation of temperature. The history was otherwise negative.

On admission her physical examination revealed a good deal of emaciation of her arms, face, and thorax. There were spider telangiectases over the face and thorax. The veins in the epigastrium were dilated. Sclerae and skin were jaundiced. Abdomen was large with some herniation of the umbilicus and there was shifting dullness. The liver edge was easily felt about a finger-breadth below the costal margin. The spleen was not palpable. There was edema of the vulva, legs and feet. There was marked hyperesthesia of the feet and general tumor of the hands. Mentally she was definitely disoriented and on admission had a temperature of 101° F.

Laboratory data on admission were as follows: urine negative except for large amount of bile, stool light brown in color with no occult blood. Red count 3,520,000, hemoglobin 70 Tallqvist (?). White count 18,000. Differential not remarkable. The red cells showed slight achromia and polychromatophilia with some variation in size and shape. Hinton was negative. Icteric index 40. Quantitative van den Bergh 15 mg. per 100 cc. Serum protein 5 per cent.

It was felt that the patient was suffering from hepatic insufficiency, probably in the nature of a subacute yellow atrophy superimposed on an alcoholic cirrhosis. Treatment was outlined as follows: complete rest in bed, avoidance of alcohol, a diet consisting of high carbohydrate, low fat, maintenance of protein. Intravenous glucose therapy was instituted and the patient was given 2000 cc. 10 per cent glucose in normal saline solution.

During the first few days in the hospital the patient was extremely irrational and had a typical Korsakoff syndrome. Mental symptoms were controlled with paraldehyde and subsided after three or four days. The jaundice definitely increased during the first three weeks, reaching a peak at this time with a quantitative van den Bergh of 25 mg. per 100 cc. At the same time there was a very definite increase in the amount of abdominal fluid and the patient became rather stuporous and unable to eat except in very small amounts. Oliguria was striking during the second week of the hospital stay, the patient putting out only 10 to 20 ounces of urine a day during this period. Ten days after admission she weighed 138 pounds, or 10 pounds more than when she entered the hospital. Because practically all the veins were thrombosed it was necessary to discontinue the intravenous glucose therapy at this time.

rence of edema and ascites in association with oliguria obviously is due to a breakdown in the normal control of body fluids in their relation to serum protein, liver glycogen, and portal flow. Jaundice results from the inability of the liver to excrete bilirubin and the lack of proper fat absorption from the digestive tract is intimately associated with the inadequate supply of bile acids to the bowel. Failure of the liver to excrete foreign substances at least provides an opportunity for measuring one of the liver functions, namely, the ability of the liver to excrete dye such as bromsulphalein or rose bengal and permits us to measure liver efficiency to a certain extent. The toxemia that is so frequently present in severe liver disease may be due to a combination of many of the above factors and may be associated with such varying symptoms as drowsiness, nausea, vomiting, and purpura. Acidosis may occur either in the form of a ketosis due to starvation or because of an excessive amount of amino acids in the blood with a resulting diminution of the normal alkali reserve.

If one is to treat the symptoms enumerated above and to attempt to restore to a normal level the hepatic functions which they represent to a greater or lesser extent, one must employ certain specific measures. These are, in the order of importance, complete rest, removal of any specific poison such as alcohol, cinchophen, etc., an adequate supply of simple carbohydrate and a minimal amount of fat, moderate limitation of fluid intake, a diet that contains at least a maintenance ration of protein, transfusion as needed to combat anemia and spontaneous hemorrhage, aided by adequate amounts of iron, diuretics, and possibly alkali at times to combat an existing acidosis. The principles of such treatment have been more or less generally recognized for some years, but failure to successfully treat individual cases of severe liver disease may frequently be laid to the fact that the treatment did not include a sufficient consideration of all the above factors. It is true, however, that in the past few years cases which were given up as hopeless frequently have been successfully treated with a resulting restoration of almost normal function.

The following cases are presented in brief detail as examples of adequate and successful treatment in patients suffering from serious hepatic failure.

The first case is that of an emotionally unstable woman of thirty-nine who had had no symptoms prior to five years before admission to the hospital. At the beginning of this period she began to consume gradually increasing amounts of alcohol, finally taking about $\frac{1}{2}$ pint daily. She was habitually constipated until two years before admission at which time her bowel movements became more regular and less constipated. She had had an increasing number of digestive symptoms during this period consisting of anorexia, gas, nausea and finally vomiting. These symptoms had all increased strikingly in the year preceding admission to the hospital. Eight months before admission she noticed that her clothes were apparently too tight, as if her abdomen were becoming larger. Five months later the patient's sister noticed that her eyes were becoming yellow and associated with this there was noticeable swelling of the feet without fatigue, dyspnea, cardiac, or urinary symptoms. There was no abdominal pain at any time. During the few weeks before admission her bowel movements had become light in color. In spite of the apparent increase in the size of her abdomen she had lost 36 pounds in the last year of her present illness. Just prior to admission she consulted a doctor who told her she had a slight elevation of temperature. The history was otherwise negative.

On admission her physical examination revealed a good deal of emaciation of her arms, face, and thorax. There were spider telangiectases over the face and thorax. The veins in the epigastrium were dilated. Sclerae and skin were jaundiced. Abdomen was large with some herniation of the umbilicus and there was shifting dullness. The liver edge was easily felt about a finger-breadth below the costal margin. The spleen was not palpable. There was edema of the vulva, legs and feet. There was marked hyperesthesia of the feet and general tumor of the hands. Mentally she was definitely disoriented and on admission had a temperature of 101° F.

Laboratory data on admission were as follows: urine negative except for large amount of bile, stool light brown in color with no occult blood. Red count 3,520,000, hemoglobin 70 Tallqvist (?). White count 18,000. Differential not remarkable. The red cells showed slight achromia and polychromatophilia with some variation in size and shape. Hinton was negative. Icteric index 40. Quantitative van den Bergh 15 mg. per 100 cc. Serum protein 5 per cent.

It was felt that the patient was suffering from hepatic insufficiency, probably in the nature of a subacute yellow atrophy superimposed on an alcoholic cirrhosis. Treatment was outlined as follows: complete rest in bed, avoidance of alcohol, a diet consisting of high carbohydrate, low fat, maintenance of protein. Intravenous glucose therapy was instituted and the patient was given 2000 cc. 10 per cent glucose in normal saline solution.

During the first few days in the hospital the patient was extremely irrational and had a typical Korsakoff syndrome. Mental symptoms were controlled with paraldehyde and subsided after three or four days. The jaundice definitely increased during the first three weeks, reaching a peak at this time with a quantitative van den Bergh of 25 mg. per 100 cc. At the same time there was a very definite increase in the amount of abdominal fluid and the patient became rather stuporous and unable to eat except in very small amounts. Oliguria was striking during the second week of the hospital stay, the patient putting out only 10 to 20 ounces of urine a day during this period. Ten days after admission she weighed 138 pounds, or 10 pounds more than when she entered the hospital. Because practically all the veins were thrombosed it was necessary to discontinue the intravenous glucose therapy at this time.

On the tenth day abdominal paracentesis was performed and 3000 cc. of straw-colored fluid was withdrawn, specific gravity 1.011 but otherwise not remarkable. The following day 1 cc. of salyrgan was given intraperitoneally without effect. A day later because of the patient's very poor condition and the fact that her anemia seemed to play an important part in her condition she was transfused with 600 cc. of blood and was again transfused six days later with the same amount. Salyrgan was again administered the second day after the transfusion with a moderate diuresis but following this there was a return of oliguria and a gradual rise in temperature until it reached 103° F. after five days. At this time the patient was so ill the second transfusion was performed and this was followed by a third injection of 2 cc. of salyrgan without any appreciable result. Two days later, or three weeks after admission, a second abdominal paracentesis was done with withdrawal of 4300 cc. of fluid of the same character as that obtained the first time. A third tap was performed five days later at which time 4000 cc. of fluid were removed. Following the second paracentesis the spleen was easily felt and continued to be palpable throughout the remainder of the acute illness. Following the second transfusion the patient's appearance was distinctly improved and along with a slight drop in temperature her symptoms of anorexia, nausea, and vomiting began to subside. Coincidentally, the stools which had been clay-colored began to return to a normal color and the jaundice diminished so that four days later the van den Bergh had dropped to 20 mg. per 100 cc. Improvement was gradual from this point on, the jaundice diminishing and the van den Bergh dropping to 7 mg. per 100 cc. one month after admission, at which time the patient was putting out a slightly greater amount of urine. A fourth and final paracentesis was performed almost five weeks after admission, at which time 4 liters of fluid were removed. On the same day 2 cc. of salyrgan were given intramuscularly with a very excellent diuresis, the first that had been obtained. Eight days later a final intramuscular injection of 2 cc. salyrgan was administered, this time resulting in a diuresis which lasted for three days with a loss of 4 pounds in weight. At this time the patient was practically symptom-free, was eating well and had improved mentally to such an extent that she was essentially normal.

She was discharged from the hospital seven weeks after admission with no evidence of ascites and very slight jaundice. The urine was free from bile and the stools were normal in color. The subsequent course of the case indicated that there was a very definite underlying cirrhosis which was also borne out by the finding of a positive Takata-Ara test.

This case illustrates well the various measures which can be employed successfully in a case of extreme hepatic insufficiency. The failure of liver function was evidenced by jaundice, drowsiness, nausea, vomiting, oliguria, edema, ascites and anemia. The specific measures which were employed were the administration of adequate amounts of carbohydrate by mouth and vein, relative limitation of fluids, complete rest, removal of the toxic substances that caused hepatic insufficiency, in this instance alcohol, the use of diuretics, transfusion, and subsequently, large doses of iron.

Two points are of interest. The first was that the patient

did not begin to improve until after two transfusions, which apparently brought about clinical improvement as well as an immediate rise in the red count. The other point of interest lies in the fact that a diuresis occurred at about the time when the patient's liver began to function more efficiently. In this instance it was apparently produced by the use of salyrgan, although only after the drug had been given four times. It is worthy of note that at times salyrgan therapy has to be continued for a long time before it becomes efficacious and it may well be that a certain degree of liver efficiency is necessary before a diuresis is possible. The case also illustrates the fact that acute liver failure may be superimposed upon a symptomless or nearly symptomless cirrhosis and, if properly handled, may not be inconsistent with almost complete recovery.

The patient has completely abstained from the use of alcohol and has been extremely careful in her manner of living and eating. As a result, her strength has gradually returned and one year after discharge from the hospital she is in apparently good health with no evidence of edema, ascites, or jaundice, although the liver and spleen are still easily palpable. A second case is of interest as illustrating how thorough a recovery can be made from what is apparently complete hepatic insufficiency when treated by adequate measures.

The patient was a woman, forty-seven years of age, with a negative past history except for a mild attack of catarrhal jaundice at the age of twenty.

Four months prior to admission to the hospital the patient was bothered by joint pains and was treated with fairly large doses of cinchophen (farastan). At about the time that cinchophen therapy was initiated the patient had a severe upper respiratory infection which lasted for several weeks. Two months before admission she noted the onset of malaise, weakness and nausea and a week later noted jaundice, dark urine and clay color stools. She stayed in bed for a few days but was up and around for six weeks before admission with increasing loss of strength, increasing jaundice and itching. For three weeks before admission there was edema of the feet and swelling of the abdomen. She had, in addition, a dry cough and a pleuritic pain at the left axilla which persisted for several weeks before admission.

Physical examination showed a deeply jaundiced, fairly well-developed and nourished woman with purpuric spots over her body and excoriations from continuous scratching. There were signs of a bilateral hydrothorax and, in addition, there was obvious ascites and edema of the legs and ankles. Careful palpation showed the edge of the liver to be about 3 fingers below the costal margin and tender. The tip of the spleen was just palpable. Laboratory examinations showed a highly colored urine containing a large amount of bile,

and light brown stools. The red count was 3,900,000, the white count 7000, hemoglobin 60 per cent, differential not remarkable. A bromsulphalein test showed 85 per cent retention of the dye at the end of one-half hour. A quantitative van den Bergh showed 5.5 mg. bilirubin per 100 cc. of blood.

Treatment was instituted promptly and consisted of absolute rest in bed, discontinuance of cinchophen, a diet containing about 450 Gm. of carbohydrate a day and the intravenous administration of 1000 cc. 10 per cent glucose in normal saline. The intravenous glucose was discontinued after four days because of the striking clinical improvement. A marked diuresis was obtained after the fourth day and a high urinary output was noted from this time throughout the following eighteen days. There was a corresponding loss of weight and improvement in the signs and symptoms. Within eight days there was an actual loss of 24 pounds with complete disappearance of ascites and edema. Jaundice also rapidly diminished and at the end of three weeks the quantitative van den Bergh was only 3.5 mg. per 100 cc. and a bromsulphalein test showed only 25 per cent dye retention at the end of an hour. At this time the liver and spleen were not palpable.

Such a rapid change in a very striking clinical picture illustrates well several facts. In the first place, the physical signs were those of almost complete liver insufficiency with jaundice, purpura and abnormal retention of water in the tissues and serous cavities. The patient was seen by several consultants and all agreed that her condition was precarious. The cause of the hepatic disturbance was obviously cinchophen, a known liver poison, and very grave concern was held regarding the prognosis. In spite of this, very simple treatment was associated with a very striking reversal of the picture, with all the signs and symptoms disappearing very rapidly. In this case the three important factors undoubtedly were rest, removal of the specific toxin, and an adequate carbohydrate intake. One point to be particularly noted was the very striking retention of fluid due to liver insufficiency with a rapid restoration of normal fluid balance once the liver cells had been restored to normal function. It is also of interest to note that the patient's recovery was complete and there had been no untoward symptoms during the past four years.

Summary.—The preceding protocols bring out practically all the essentials of successful treatment of hepatic insufficiency. The two patients were critically ill from what amounted to subacute yellow atrophy. The various functions of the liver were restored to normal by the measures already stressed, namely, rest, removal of toxin, adequate carbohydrate intake, the use of diuretics, and abdominal paracentesis when

required, blood transfusion, and iron therapy. Rarely the use of alkali to combat an existing acidosis due to failure of deaminization of amino acids is indicated, but in these two instances this was not the case. By similar measures it undoubtedly will be possible to successfully treat almost any type of liver disturbance, infectious or toxic in nature, provided surgical measures are not indicated. The essential considerations are a proper evaluation of the degree of liver insufficiency, the speed with which treatment is instituted, and the thoroughness and persistency with which the various measures are carried out.

CLINIC OF DR. FREDERICK C. IRVING

BOSTON

PRENATAL CARE IN PRIVATE PRACTICE

I SHALL present for your consideration the case of Mrs. R., a primipara of twenty-two, who came to my office on January 15. Her last menstrual period began November 5 and there has been no bleeding since this date. She has always been regular in her catamenial habits since she first began to menstruate at the age of fourteen and she has never skipped a period. The flow has always been moderate in amount, appearing every twenty-eight days, and never requiring more than four pads on any one day. She never passes clots. The duration of the period is usually five days. There is no pain either just prior to the period or during its course, and there is no interference with her daily routine of life. She was married on September 5. Neither she nor her husband have taken any contraceptive precautions, as they have both wanted children.

It is apparent that Mrs. R. has had a normal menstrual history and the presumption is that she is pregnant. The next step is to ascertain if she has any of the other early subjective evidences of gestation. She says that about a month after missing her first period she began to have considerable nausea on awakening and that on several occasions she has vomited her breakfast. This condition still persists. When questioned regarding the condition of her breasts, she states that they are tender and distinctly enlarged. She has to urinate more frequently during the day and must arise for this purpose once during the night, which has never been the case before. She is sleepy at times and finds herself taking naps during the afternoon.

Before proceeding to a physical examination it will be convenient at this point to go into the patient's past history.

Both her parents are living and have had no serious illnesses. She is the oldest of three children. She had measles in childhood and has had her tonsils removed twice. An appendectomy without drainage was performed at fourteen. She has had no other surgical operations, nor has she broken any bones. She has never had scarlet fever, diphtheria, pneumonia, rheumatic fever or heart or kidney disease. Since the removal of her tonsils she has not been subject to sore throats or colds. Her weight has not varied much for the past two years. She plays ordinary games for pleasure but does not consider herself particularly athletic.

The patient is of medium height and weighs 120 pounds. General examination reveals nothing of interest. Her teeth are good. Examination shows the second laryngological attack upon her tonsils to have been victorious. The heart and lungs are normal. The breasts show no abnormalities, but the veins underlying the skin are prominent. The nipples project from the areolae, which contain a number of enlarged Montgomery's tubercles. The abdomen is negative, save for a linear scar about 2 inches long in the right lower quadrant. There are no herniae. The fundus of the uterus is not felt above the symphysis nor are any abdominal tumors made out.

The feet are placed in stirrups, the legs draped with a sheet. My nurse washes her hands and then prepares the vulva with cotton pledgets soaked in mild soap solution and warm water. I wash my hands and draw a dry sterile glove onto my left hand. Strict surgical asepsis is not necessary for such an examination. The labia are separated with the right hand: the mucous membrane of the introitus is slightly blue. The left forefinger, well covered with surgical lubricant, is gently introduced into the vagina, being particular to avoid the clitoris, which may be quite sensitive. I find by bimanual examination that the uterus is slightly enlarged and somewhat soft. The tissue about the external os is velvety in texture. Mrs. R., who is somewhat apprehensive, contracts her abdominal muscles so that further investigation is impeded, although she says that I have not hurt her. I therefore direct my nurse to raise the head of the table and I ask the patient to breathe deeply. These expedients have the desired effect. I am now able to introduce both my fore and middle fingers

and palpate bimanually each time the patient expires. I find that there is a distinct softening at the isthmus of the uterus, the so-called "Hegar's sign." I can feel the left ovary, which appears normal; the right I cannot make out. I reach cautiously for the promontory of the sacrum but am unable to touch it. The vaginal examination is completed by the introduction of a well-lubricated vaginal speculum. The portio vaginalis is distinctly purplish, the external os is nulliparous in form; the discharge is clear mucus and normal in amount and there are no cervical polyps visible.

With the patient in the same position I palpate and measure the pelvic outlet. The symphysis is of normal height and inclination; the arch is wide, being Roman rather than Gothic in architecture. I show Mrs. R. the outlet pelvimeter, and tell her that from now on I shall take measurements only, that there will be no further internal examination and that she will not be hurt. I insert my thumbs in the rings of the pelvimeter and place them upon the ischial tuberosities. The widest measurement so obtained is the correct one. I find it to be 10 centimeters, which is quite normal, and then measure Schuman's pubotuberous diameter, which is obtained by placing one tip of the large pelvimeter upon the left ischial tuberosity and the other upon the top of the pelvic bone. This distance is 10.5 cm., which is also normal. So far I have found that the pelvis is not male or funnel in type, since the outlet is not contracted nor is its height greater than one would expect in a normal woman.

The leaf at the foot of the table is raised and the patient's legs extended upon it. The legs are covered and the abdomen exposed. I place the tips of the pelvimeter upon the widest point of separation of the iliac crest and find it to be 28 cm. I then lay them upon the most prominent portions anteriorly of the iliac crests and make this measurement 25 cm. I ask Mrs. R. to lie on her left side and to bend the left knee, while she keeps her right leg straight. I identify the spine of the last lumbar vertebra and place one branch of the pelvimeter just below it while the other rests upon the anterior surface of the symphysis. I so obtain the external conjugate, which is 20 cm.

All of Mrs. R.'s measurements of the upper pelvis are nor-

mal. In general it may be said that whatever are the actual measurements, the interspinous is usually 3 cm. less than the intercrystal and the external conjugate 5 cm. less than the interspinous. When these proportions do not hold either there is gross pelvic deformity or, as is more frequently the case, the examiner is in error. The distance between the trochanters of the femora is not taken, because the measurement is of no value.

In spite of the information we have obtained regarding this patient's pelvis we have no real knowledge concerning the size of the interior, which is what interests us most, since the external measurements bear no close relationship to those within. However, since Mrs. R.'s long bones are normal for a woman of her height and weight, we may assume that her general skeletal development is also normal and that there is no reason to fear pelvic contraction. Accurate information concerning the interior of the pelvis can be obtained only by determining the diagonal conjugate, which, in Mrs. R.'s case, was impossible without anesthesia, or by x-ray measurements. x-Ray measurements are not indicated as a routine and are only of value at the end of pregnancy if the presenting part does not enter the pelvis.

I inform Mrs. R. that she is presumably pregnant. She wishes to know if more definite information can not be obtained by performing the "rabbit test," about which one of her friends has told her. The reply is that the lapse of time will give an equally accurate answer and at no expense. There seems to be a tendency at present to perform the Aschheim-Zondek test in cases where an immediate diagnosis is not essential. This probably results from a desire to employ so-called "methods of precision" and to avoid making a diagnosis on the basis of skill and personal experience. It should be remembered that the Aschheim-Zondek test and its modifications are not invariably accurate and that false negatives have on some occasions been reported in early pregnancy.

Mrs. R. is then instructed regarding prenatal care. She is directed to come to the office every month until the last three months of her pregnancy, after which she will be expected to report every two weeks. An appointment is made for her next visit and a card bearing the date and hour is

given to her for a memorandum. The nurse, who reports that the specimen voided in the office is normal, gives her a small clean bottle containing a few drops of chloroform as a preservative and enclosed in a mailing case. She is instructed to place in the bottle a mixed day and night specimen of urine, obtained by saving what she voids on going to bed, and what she passes during the night and on arising in the morning. She is also warned to place in the mailing tube a slip of paper bearing her name, since the identification of unmarked specimens is difficult, if not impossible. These specimens may be sent conveniently by mail. When they arrive at the office the color, reaction, and specific gravity are noted. The filtered urine is tested for albumin by the nitric acid method. If a suspicious ring is obtained the heat test is performed on a specimen. If albumin is found the centrifuged sediment is examined microscopically. The urine is always tested for sugar, since only in this way can the presence of latent diabetes be detected. If a reducing substance is found it may be glucose or lactose. Yeast ferments glucose but not lactose. A blood sugar determination is indicated when a positive sugar test is obtained.

It is well to follow a definite routine in instructing new patients so that nothing essential will be left out. The instructions apply to diet, care of the bowels, exercise, rest, clothing, bathing, and end with a brief recapitulation of the untoward events which should lead the patient to consult the doctor immediately.

Mrs. R. informs me that she has a considerable amount of nausea and that she occasionally vomits in the morning. She is told to eat two unsalted crackers and to drink a little water or a cup of black coffee before rising and to stay in bed half an hour thereafter. Her breakfast is to be a small one, consisting of cereal, dry toast and coffee; or a boiled egg, dry toast and coffee with orange juice. At 10:30 A. M. she has a slice of bread and butter and a glass of milk or a cup of cocoa. At 1.00 P. M. she has her luncheon, which may consist of soup or broth, a green vegetable or salad, bread, toast or rolls. At 4:30 P. M. she has tea. In addition there is toast, or bread and crackers with strained honey, jam or marmalade. At 7:00 P. M. she has a light dinner consisting of meat and vegetables

with soup or dessert. Before retiring Mrs. R. has a glass of milk or a cup of cocoa with bread or crackers. All fats, such as cream, or an excess of butter, or olive oil in salad dressing, are avoided; also fat meats, as bacon, ham, pork, certain fishes (salmon, herring, mackerel, bluefish). No food should be fried. On the other hand, carbohydrates may be given freely, including those containing sugar. Lean meat has no harmful or beneficial effect.

The patient is told to go about her daily activities with as little regard to her nausea as possible. She is asked to report by telephone if she does not improve within a week and is told that if she still feels ill a prescription will be sent her. This will consist of sodium luminal, $\frac{3}{4}$ grain, to be taken twice or thrice daily.

Mrs. R. says that she has always been constipated and that this condition is even more marked since she has skipped her periods. The necessity of regular daily bowel movements is impressed on her. She is told that green vegetables, whole wheat bread, bran, cereals, 6 to 8 glasses of water daily and the habit of using the toilet at the same time every day will do much to set things right. If a laxative is needed it is administered preferably at night in pill or tablet form, as less likely to provoke nausea. Mineral oil, while excellent, is more appropriate later in pregnancy, when the stomach is in a more receptive condition.

Many dentists believe that the administration of calcium and vitamin D will prevent dental caries. Two glasses of milk, about 500 cc., contain 0.5 Gm. of calcium, which with the amount obtained in other foods should be enough for the needs of the fetus. If the patient does not like milk or if the physician fears that its ingestion will produce too marked a gain in weight, calcium may be provided in the form of gluconate or a similar absorbable form. Vitamin D may be given in any of the standard preparations.

The patient is told to forego all forms of athletic exercises, but to take a walk every day, lasting from half an hour to one hour. She is not to lift heavy objects or reach for things on high shelves or hooks which may require her standing on tiptoes. She may take warm baths, but is to avoid those which are very hot or cold. She is to mark off on a calendar

the days when she would be menstruating if she were not pregnant and is to avoid intercourse, undue exertion or social activities at those times. She is to take a rest every afternoon and to be in bed by 10 o'clock except when she goes out in the evening for entertainment, which should not be more than twice a week.

Her clothing should be appropriate to the season. Constriction of the waist is avoided and clothes are to be hung from the shoulders. Round garters or rolling the tops of the stockings may predispose to varicose veins. Shoes should be comfortable with moderately low flat rubber heels. If she habitually wears a girdle she may continue to use it until it becomes too tight. Later a maternity support may be required, but this depends solely upon the patient's comfort and confers no particular benefit upon the mother or child. Should it be necessary to order such a support the patient is sent to a corsetiere who will carry out the doctor's wishes. Many dealers in such garments, if not checked, will sell the patient an elaborate and expensive corset which is only of use to very large, stout women.

Mrs. R. is told that she is to report by telephone immediately and go directly to bed if she has any vaginal bleeding or abdominal pain. She is also informed that she is to consult me freely if anything occurs which she does not understand or if she wishes any advice. She is cautioned against the medical lore of her married relatives and friends. At this time also she is warned of the other danger signals of later pregnancy which are indicative of toxemia such as headaches, blurring of vision, abdominal pain and swelling of the face or extremities.

Over half an hour has been spent at the first call. Subsequent visits will require less time, as it will only be necessary to take the patient's blood pressure, weigh her and ask her certain routine questions. In early pregnancy these concern bleeding, abdominal pain, the frequency with which her bowels move, and the general state of her health. At the beginning of the second half of pregnancy one should ascertain the date of quickening and from this information calculate expected date of confinement to see if it agrees with that obtained by counting from the first day of the last period. In the event

of a marked discrepancy between the two dates, more reliance should be placed upon calculation from the last menstruation, since the first detection of fetal motions is entirely subjective and introduces an element of individual variation.

If all is going well it is not only unnecessary but an annoyance to examine the patient every time she comes to the office. Any symptoms, however, should be carefully investigated. About two months before term the abdomen should be palpated to detect a possible breech presentation, since an external version may be more easily accomplished at this time than later in pregnancy. Three or four weeks before the expected date of confinement the patient is examined vaginally under strict aseptic precautions. The presenting part is identified and its station in the pelvis determined; whether it is low, mid, high or floating. One notes whether the portio vaginalis is shortened or effaced, the consistency of the cervix and how many fingertips the external os and the internal os admit. The diagnosis of position is made almost entirely by abdominal palpation. The fetal heart tones are ausculted. About this time the patient may ask if the baby is going to be a boy or a girl. The truthful physician will tell her that he does not know. If he ventures into the realm of prophecy he will be wrong half the time. A large uterus with confusing fetal landmarks, even though only one fetal heart is heard, warrants an x-ray examination to settle the question of twins. It may startle the patient and her husband as well as embarrass the doctor at the time of delivery if nature's generosity is not known beforehand.

Nothing more is heard from Mrs. R. until two weeks later, when she telephones to say that she has noticed the escape of a small amount of bright blood from the vagina, in all, less than a teaspoonful. There is no pain and she is now in bed. I tell her not to get up and that I shall see her as soon as possible. I also inform her that I shall want her to remain in bed for some time and that I shall send a nurse to her house to care for her. Since the original pelvic examination revealed no masses or abnormal tenderness it is unlikely that the bleeding indicates an ectopic pregnancy; rather are the chances in favor of a threatened abortion.

I find the patient in bed and perfectly comfortable. There

is a little fresh staining on the vulvar pad. I do not make a vaginal examination for fear of loosening further the ovum from its attachment. I cautiously palpate the lower abdomen. I feel the fundus of the uterus just at the symphysis pubis, which is commensurate with the estimated duration of pregnancy. There is no tenderness anywhere. She says she still feels slightly nauseated but that things have improved greatly. I instruct the nurse to keep Mrs. R. in bed. She is to use the bed pan instead of the toilet. She may have two pillows but is not to sit up. No attempt is made to move her bowels for twenty-four hours, when she is to have an oil enema, to be followed later by mineral oil by mouth. Most authors of textbooks advise the use of morphine in threatened miscarriage to diminish uterine irritability, but this therapy seems to be based on a misconception of the mechanism of miscarriage. The first step in abortion is bleeding into the spongy layer of the decidua basalis. It is not until the hemorrhage becomes of sufficient extent to distend the uterus or separate the ovum that the uterus reacts and attempts to expel the product of conception. It is therefore difficult to see what beneficial effect morphine can have in preventing the completion of an abortion, although its use is justified to relieve pain when an abortion is actually in process. The application of an ice-bag to the suprapubic region can do nothing unless it is to stimulate uterine contractions, which is what we wish most to avoid.

Mrs. R. remains in bed for one week after all bleeding has stopped. The first day up she is allowed to sit in a chair; the next day, although restricted to the same floor, she may walk about and the third day she may go downstairs to dinner. Her activities are gradually expanded and the nurse is omitted. On wholly empirical grounds the patient is given a half a grain of thyroid extract daily and is encouraged to eat articles containing vitamin E, such as lettuce, corn, and wheat germ. If the attendant wishes he may attempt to increase the amount of progesterin (corpus luteum hormone) by administering a suitable glandular product, if he realizes that there is at present no convincing clinical experience to justify him in his course of treatment. Intercourse, exertion, travel and auto-mobiling are forbidden for at least a month.

For the present Mrs. R.'s pregnancy progresses normally.

At her visit of April 9 I find that she first felt the baby move on March 24. Since she is a primipara I add twenty weeks to this date and find the expected date of confinement to be August 11, which agrees well with the date of August 12 obtained by calculation from the first day of the last period. She feels very well indeed and is evincing interest in food.

On May 7 I find that Mrs. R. has gained 5 pounds since her last visit. Her urinalysis and blood pressure readings are normal. The question of diet is discussed in some detail. She has been to visit her mother, who has urged her to eat large quantities of food so that she may have a nice, large, healthy baby. Patient explanation at least partially convinces Mrs. R. that the amount of food she eats will have very little effect on the size of the baby, but will have a very considerable effect on her. She is told that an accumulation of fat will make it more difficult for her to give birth to the baby and that it may make the difference between a normal and an operative delivery. The final argument that a great increase in weight may spoil her figure appears to produce some impression. She is told to weigh herself twice a week on the same scales and not to gain more than half a pound a week. A printed diet list is given her, showing the caloric value of various foods and she is instructed to restrict her daily intake to 2000 calories. She is especially cautioned against an excess of fats, sweets and starches.

At Mrs. R.'s next visit on May 21, I find that she has attended faithfully to her diet and has only gained $1\frac{1}{2}$ pounds in two weeks. She complains of constipation and heartburn. She is told to eat plenty of fruit, green vegetables and whole wheat bread. A suitable preparation of bran is advised for breakfast. She is instructed to cultivate regular hygienic habits and to drink an adequate amount of water, 6 to 8 glasses daily. A tablespoonful of mineral oil is prescribed half an hour before each meal and at bedtime, with instruction if the oil should escape by rectum to reduce each dose, but not the total number of doses. For the heartburn calcium carbonate is prescribed in 5 grain tablets to be carried with her and taken *ad libitum*. She is also cautioned to avoid spiced, fried or highly seasoned foods and is warned that no per-

manent improvement may be expected until after the birth of the baby.

On July 16 Mrs. R. has her antepartum examination. The portio vaginalis is shortened but not completely obliterated; the external os admits a fingertip, but the internal os is closed. The lowest part of the vertex is just above the imaginary line joining the ischial spine. Abdominal palpation also shows the head to be engaged, the fetal small parts are felt in the right flank and the fetal heart is best heard on the left. The position is left occiput anterior. The uterine fundus is almost at the costal margin.

On July 30 I find that Mrs. R. has gained 6 pounds in the last two weeks. Her ankles are slightly puffy and her face is beginning to have the full appearance characteristic of edema. The blood pressure is 120/84 and the urinalysis is negative. However, the sudden increase in weight is suggestive of an approaching toxemia. She is told to take a tablespoonful of Epsom salts in water after returning home and to take the same dose morning and evening of the next day. Meat, fish, eggs and salt are eliminated from her diet and her fluids are restricted to 4 glasses of water daily. She is told to return in two days and to telephone at once if she has any headaches, blurring of vision, double vision, specks before the eyes, abdominal pain or increase in the swelling of her face, hands or feet.

She returns in two days and looks slightly improved. There is less facial and dependent edema and she has lost 3 pounds. The blood pressure has risen to 150/96. The urine is more concentrated, but it still contains no albumin. However, the hypertension is sufficient to alarm me and I tell Mrs. R. that I want her to enter the hospital that day so that we may treat her more thoroughly and observe her constantly. She wants to know if it will not be satisfactory to carry out the same policy at home. She is informed that this cannot be done and that her interests and those of the baby demand the best possible care. She says that she must confer with her husband and will let me know her plans later in the day.

After she has left the office I call her husband on the telephone and discuss the situation. I describe to him briefly the nature of eclampsia and tell him that it is practically a

preventable disease but that I must have his and Mrs. R.'s cooperation if I am to take the responsibility. He informs me that I may count on them both and she enters the hospital that evening.

When the patient is admitted she is put to bed and is not allowed up until it is so ordered. A catheter specimen of urine is obtained for examination and a blood sample for the determination of the nonprotein nitrogen, urea nitrogen and the uric acid. The first day she is given nothing by mouth but 600 cc. of water. The next day a milk diet is begun to the extent of 800 calories, which is gradually increased up to 1600 calories. The fluid output, including liquid feces, is measured. In no event is the fluid intake allowed to exceed the output. Immediately on entrance 1 ounce of a 50 per cent or saturated solution of magnesium sulphate is given by mouth and is repeated every hour unless the patient is asleep. This is continued until there are from 12 to 13 watery stools a day after which the frequency of the dosage is reduced. Few women whose bowels are moving freely develop eclampsia.

The limitation of fluids and the vigorous catharsis produces a marked reduction in the edema so that Mrs. R. loses 8 pounds more. Her face is less puffy and the pitting edema over her ankles has largely disappeared. The blood examination shows: N. P. N. 30.00, B. U. N. 14.00, U. A. 4.00, which is not remarkable. The blood pressure falls the day after admission to 130/90 and remains in that general vicinity. There are no headaches, visual disturbances or epigastric pain. The urine, which becomes quite concentrated, shows a trace of albumin and the sediment reveals hyaline and granular casts with occasional red blood corpuscles. The amount of albumin varies from day to day, but is never less than a slight trace.

It is evident that Mrs. R.'s condition has improved since entering the hospital but that she has not completely recovered, nor is she sufficiently improved to permit her return home. There seems to be no immediate danger of convulsions, but since preeclampsia is followed in a considerable number of cases by permanent vascular hypertension we must consider the advisability of terminating pregnancy. The child is practically mature, being within the last two weeks of pregnancy and there is no cephalopelvic disproportion. Exam-

ination shows the portio vaginalis to be effaced and the os one fingertip dilated. Accordingly, Mrs. R. is given 2 ounces of castor oil early in the morning and an enema two hours later. Her membranes are then ruptured artificially under strict aseptic precautions. Within an hour uterine contractions have begun and the delivery of a normal infant weighing $6\frac{1}{2}$ pounds occurs in the evening.

Mrs. R.'s subsequent course is uneventful. Her blood pressure falls after delivery to 120/74. A catheter specimen of urine a week postpartum contains only the slightest possible trace of albumin and the sediment is negative. A similar specimen on discharge from the hospital contains no albumin. When she was seen six weeks and six months after delivery her condition was normal in every way.

CLINIC OF DRS. WILLIAM E. LADD
AND LEROY D. FOTHERGILL

CHILDREN'S HOSPITAL

IDIOPATHIC ULCERATIVE COLITIS IN CHILDREN

Definition.—Idiopathic ulcerative colitis is a disease not only difficult to treat but difficult even to define adequately. The patients whom we would include under this title are those who suffer from a chronic bloody mucous diarrhea, and who show ulcerative lesions in the colon for which no etiologic factor can be found. The disease may be mild or severe. It occurs most commonly in early adult life but is not infrequently found in the first twelve years of life, and it is with this age group that this paper is concerned.

Etiology.—In our opinion the etiology of the disease is still unsettled. Numerous theories have been advanced to explain it. The disease is generally believed to be of infectious origin. Numerous bacteria have at one time or another been considered to cause the disease. Barger has presented a good review of the literature, and the possible bacterial etiology of chronic ulcerative colitis, and described a diplococcus known by his name as the causative organism. We do not feel that the evidence is sufficient to accept the Barger diplococcus as the cause of the disease.

Twenty-three of the patients of our series have had a detailed bacteriologic study. Cultures were taken from stools and also in many instances directly from ulcerations at the time of proctoscopic examination. The study of these cultures has not shown the consistent presence of any one organism to which pathogenic significance could be attached.

The Barger diplococcus was isolated in 8 instances and a late lactose fermenting organism, similar in its other cultural characteristics to the paratyphoid group, was isolated

from 2 patients. In 1 patient cultures taken directly from the ulcers showed a hemolytic streptococcus and a Bagen diplococcus.

Pathology.—The ulcerative process of the colon in this disease is of characteristic appearance though subject to variation in amount and extent of distribution. It commonly involves the rectosigmoid segment and descending colon but may be extended to the whole colon and an occasional case has been reported in which the lower portion of the ileum was also involved. The ulcerations are typically small and placed close together leaving very little mucous membrane unaffected, and giving in the gross a red granular appearance rather than widely separated individual ulcers. As the disease progresses the ulcerations extend to the deeper layers of the colon, replacing the muscle layers with scar tissue or eventually, at times, penetrating all layers and resulting in perforation and localized abscesses or peritonitis. The remote systemic findings consist in general emaciation, loss of weight, and in cases of long standing, a secondary anemia which may be of considerable severity. One or two of our patients have presented bizarre skin lesions and joint changes.

Symptoms.—The onset of the disease in children is usually insidious, although occasional cases may have an abrupt onset. Usually the first symptom noted is a gradually increasing frequency of bowel movements. These are often accompanied by cramps and abdominal discomfort. As time goes on the bowel movements become more frequent and mucus, often in considerable amounts, appears in the stools. Later, when numerous ulcers have appeared, the stools contain considerable pus and blood in addition to mucus. The number of watery bowel movements containing these abnormal elements usually varies from five to fifteen daily, although in some patients they may be much more numerous. Many such patients run a low grade fever although some may have normal temperatures. Because of the almost continuous loss of blood in the stools, the symptoms and blood changes of a moderately severe anemia are found.

The symptoms may continue unabated or with periodic remissions, for months or even years, during which time marked structural changes are occurring in the colon. Such patients

lead a very depressing and miserable existence. The more severe cases may be confined to bed. The less severe cases, while not bedridden, become social outcasts. They are unable to attend school or engage in the usual play of their associates because of the embarrassing frequency of bowel movements.

As the disease continues the nutritional state of the patient becomes increasingly poor. A great deal of weight is lost and marked retardation in growth and development occurs. There is usually fairly good compensation for the disturbances in water and electrolyte metabolism. This is probably because of the chronicity of the disease.

Physical Examination.—On general physical examination of these patients with idiopathic ulcerative colitis one does not find any definite characteristic except the general emaciation due to the wasting process and the pallor due to the secondary anemia. Occasionally on abdominal examination tenderness is elicited by pressure along the course of the colon. Proctoscopic examination in contrast to the general examination is quite characteristic. When the proctoscope is introduced one will see first a considerable amount of grayish, mucopurulent material. When this is washed or gently wiped away the mucous membrane appears red and granular with minute ulcerations diffusely scattered over its surface. The mucous membrane bleeds easily on very slight trauma. Perhaps the most striking characteristic of the proctoscopic examination is the fact that one sees almost no normal-appearing mucous membrane in contrast to other types of ulcerative colitis.

Laboratory.—*x*-Ray examination of a barium enema shows a characteristic change from the normal as soon as structural change has taken place in the colon. Early in the disease the haustral markings become shallow and infrequent, and later in the disease are entirely absent, giving what is usually described as a pipelike appearance. The bacteriologic findings in the stools will be considered as a part of the differential diagnosis.

Diagnosis.—The diagnosis of idiopathic ulcerative colitis is suspected in any patient with a history of chronic bloody mucous diarrhea who presents a characteristic picture on proc-

toscopic and x-ray examinations and after other conditions have been eliminated by suitable bacteriologic studies.

There are several conditions which have to be considered in the differential diagnosis. In children the most important conditions to be considered are amebic dysentery, tuberculous enteritis, chronic bacillary dysentery, and rarely Meckel's diverticulum. The acute diarrheas such as those caused by the dysentery bacillus and certain members of the paratyphoid group of organisms are seldom confused with chronic ulcerative colitis because of their acute onset and relatively short duration. Diarrhea associated with certain deficiency diseases such as pellagra, beriberi, or sprue should be considered through taking a detailed dietary history and seeking other clinical evidences of these disturbances. Malignant disease, diverticulitis, and polyposis are rarely seen in children and therefore do not as frequently offer a problem in differential diagnosis as in adults. Since the etiology and pathogenesis of chronic ulcerative colitis is not clearly understood, it is very important to exclude the above conditions before arriving at its diagnosis. In part, the diagnosis is arrived at by a process of elimination.

Amebic dysentery can be ruled out only by the careful examination of a considerable number of stool specimens by someone familiar with the appearance of both the cysts and vegetative forms of *entameba histolytica*. It should be emphasized that to be of value, stool examinations for ameba should be done as quickly as possible after the stool is passed. Furthermore, at the time of proctoscopic examination of a patient suspected of ulcerative colitis, material should be taken directly from the ulcers and examined immediately for amebae. In occasional cases with a suggestive history, such as residence in the tropics, but with repeatedly negative stool examinations for amebae, it may be worth while to treat the patient with some emetine preparation as a therapeutic trial.

The tuberculin test is of great value in the differential diagnosis of tuberculous enteritis *in children*. If this test is negative to the larger doses of tuberculin (*i. e.*, an intracutaneous injection of 1 mg.) it is reasonably certain that the enteritis is not of tuberculous origin. However, if the reaction is positive, a detailed and careful study is necessary.

Tuberculous enteritis usually involves the upper end of the large bowel or terminal ileum, and may be demonstrated by x-ray examination. Direct smears of fecal material, concentrated by antiformin, should be examined, and with negative results, such material should be injected into one or more guinea-pigs.

A true chronic bacillary dysentery is extremely rare in children, at least in our experience. It is ruled out by the repeated culturing of fresh fecal material. It should be emphasized that a number of stool cultures are necessary. A single negative culture is of no value whatever. Agglutination reactions with the patient's serum and a large number of stock antigens are of value. A large group of antigens should be used because there are so many serologically different strains of dysentery bacilli. In our own agglutination studies we use, in addition to the dysentery antigens, a number of different strains of organisms belonging to the paratyphoid group.

The symptoms presented by patients with a Meckel's diverticulum may, in an occasional instance, be confused with those in early cases of chronic ulcerative colitis. In the former disease bleeding into the bowel is not uncommon and occasionally diarrhea may be present. In such patients, changes in the colon are not demonstrable by x-ray following a barium enema and ulcers are not visualized at proctoscopic examination.

When a patient is admitted to this clinic with a history suggesting chronic ulcerative colitis the plan of diagnostic study carried out is as follows: the patient is kept at complete rest in bed and is given a low residue diet. The usual routine examinations such as complete physical, blood, and urinalysis are done. If the patient is febrile, one or more blood cultures are taken. Blood is also taken for a Wassermann reaction and for serum for agglutination with these antigens; B. dysentery Shiga, B. dysentery Flexner, B. dysentery Hiss-Russell, B. dysentery Sonne, B. paratyphosus A, B. paratyphosus B, B. enteritidis, and B. abortus.

Several freshly passed stool specimens (4 or more) are examined for the presence of *entameba histolytica* and for the cysts of this parasite as well as being cultured for pathogenic organisms.

Intracutaneous tuberculin tests are done starting with 0.01 mg. of tuberculin. If the reactions are negative to the smaller doses, the dosage is increased to 1 mg. of tuberculin. If the tuberculin reaction is positive a thorough search is made by roentgen ray for any parenteral focus of infection. Stool specimens are carefully examined for tubercle bacilli by the methods described above.

The colon is examined by roentgen ray following a barium enema in order to appraise the amount, location, and characteristics of any structural change that may be present.

The child is finally subjected to proctoscopic examination (under anesthesia) in order to visualize any ulcers that may be present. At this time material is swabbed directly from the ulcers for smear examination, ameba search, and cultures.

The diagnosis of idiopathic chronic ulcerative colitis is arrived at only after all the data from such a study has been collected.

Treatment.—After a diagnosis of idiopathic ulcerative colitis has been reached the question of what form of treatment should be employed naturally arises. On this subject there is little uniformity of opinion at the present time either as regards the general principles or the details. This situation has arisen for two reasons, one that there is a wide variation in the severity of the disease and, two, that in the more severe types of the disease no form of treatment is uniformly successful or curative. Broadly speaking, medical treatment is employed for a limited period of time for those patients in whom the diagnosis is doubtful or in whom the disease is mild and has been present for a short time only. The medical treatment consists of rest and general good hygiene. The patient is placed on a low residue diet containing an adequate amount of the essential vitamins. If the secondary anemia is marked it is combated by a soluble form of iron and transfusions. The use of opiates to control diarrhea is of doubtful wisdom on account of the chronicity of the condition. Such drugs as bismuth subnitrate or subcarbonate have been found to be of little value in our experience. Colonic irrigations are not of value, are painful, and must be dangerous on account of the possibility of causing perforation if the disease is of long duration. Autogenous vaccines made either from cultures of

the Bargaen diplococcus or other organisms isolated from the feces of these patients have been of no therapeutic value in our experience. The use of a serum would seem somewhat illogical until such time as the causative organism has been proved beyond peradventure.

The question of the indications for surgical treatment and what form of operation should be done is again one that lacks uniformity of opinion. It is our belief that the unpleasantness of the operation has in most instances caused an unwarranted delay in its adoption. This delay has removed any possibility of curing the disease. We believe that the almost universal prolonged persistence of medical treatment of one form or another accounts for part of the usual pessimistic surgical point of view. There are two logical reasons for resorting to surgical treatment. The first is to save the life of a patient who is going downhill rapidly during the course of the disease. The second is to limit the progress of the disease and improve the patient's general condition, removing him from a state of chronic invalidism. The operation which we advocate for fulfilling these reasons is transverse ileostomy with complete external diversion of the fecal stream. We have had no experience with appendicostomy, cecostomy, or colostomy, but feel that there is not sufficient evidence of their merit in the literature to warrant their employment. It cannot be claimed that ileostomy is a pleasant operation or that it can be performed without risk. It can be claimed, however, that it is at times a life-saving procedure and that the inconvenience and drawbacks of an ileostomy are less than those of the disease.

There have been 26 patients treated at the Children's Hospital on whom a diagnosis of chronic ulcerative colitis has been made. Of these 26 patients 10 have received medical treatment only. Three of these 10 in whom the symptoms were rather mild and of short duration, have apparently recovered and stayed well for variable periods of time. Whether they will later have remissions is a matter of surmise. The other seven still have the disease and have not been improved by the various forms of treatment used, including autogenous vaccine therapy. The remaining 16 patients have all had medical treatment without improvement for periods of several

months to several years before resorting to surgical treatment. There are two exceptions to this statement in the cases of two infants who will be referred to presently.

Though the results of the surgical treatment in this series are far from gratifying, still there are features in the series which are hopeful and which lead to the belief that the results may be improved.

All of these 16 patients have had an ileostomy performed. Four who had had the disease from five to two years before operation, had the ileostomy closed, in one instance eight years later and in the other three about two years after ileostomy. These 4 patients have been followed afterwards for four years and eleven months, three years and nine months, two years, and one year and two months respectively. They were all having normal stools, were in good general condition and so far as we could gather, were, for the time being, well. Whether they will eventually have remissions is, of course, impossible to say. Perhaps of more significance than these 4 cases is the history and unfortunate end-result in a boy who had an ileostomy performed when he was nine years and ten months old. This boy had a history of bloody mucous diarrhea for over seven years, not as severe as in some of the other patients, but increasing in severity during the six months prior to the ileostomy. He had 6 to 8 stools daily with blood and mucus, and he was losing weight. The proctoscopic examination revealed the characteristic ulcerations, and barium enemas given at six-month intervals showed increasing structural change of the colon. Subsequent to the ileostomy he improved rapidly, gained 17 pounds in weight in the first six months, went to school, indulged in active exercise, and in short, lived a very normal life. At the end of two years, closure of the ileostomy was being considered when he developed a volvulus of the jejunum with acute intestinal obstruction from which he died. The notes of the postmortem examination of the colon are of interest. Gross examination, "The mucosa of the colon appears to be practically normal except for a very fine roughening of its surface. It is not injected and there are no areas of ulceration. Hanging from the serosa of the colon are a number of small appendices epiploicae." Microscopic examination of the colon. "There is a single layer of

columnar epithelium over practically the entire surface of the colon. The mucosal surface is remarkably smooth. The glands are rather small, but their epithelium is remarkably well preserved. The tunica propria is infiltrated with a moderate number of large and small mononuclear cells and a few polymorphonuclear leukocytes. There is slight congestion here also. The solitary follicles are markedly depleted of lymphocytes and infiltrated moderately by large mononuclear cells. There are fairly numerous small areas of necrosis just under the intact epithelial surface. One healed ulcer now covered by epithelium is noted." The pathologist, Dr. Farber, comments, "The findings here are of great importance in reference to the efficiency of the rest treatment of the colon by surgical means. Certainly there was no evidence of an active ulcerative colitis at the time of autopsy."

Besides the 4 patients who had the ileostomy closed and were at the last report apparently well, there are 5 patients in this series who have the ileostomy still open. One boy who had had the disease since he was ten years old, had an ileostomy at fourteen years of age. He was very emaciated, weak, confined to bed, and in very poor general condition. Following the ileostomy his condition improved markedly. He gained weight, was able to be up and lead a fairly normal life. Three years later proctoscopic examination revealed an active process in the colon. This patient may be a candidate for colectomy. He is not a candidate for closure of the ileostomy. Another patient who had had the disease only eight months when the ileostomy was performed, had a rather stormy course for a few weeks following operation, but at last note, eighteen months later, was in excellent condition. This patient may be able to have the ileostomy closed later. A third patient, a girl, contracted the disease at the age of eight, and the ileostomy was performed four years later, when she was in very poor condition. During her convalescence she developed a very extensive ischio-rectal abscess. Examination two years later showed the patient in excellent general condition. We believe the ileostomy in this instance was a life-saving procedure, even though the disease is still present. Proctoscopic examination at this time revealed some mucopurulent discharge, a mucous membrane that bled on very slight trauma,

one small polyp, and an anal sphincter of doubtful competence. We believe this girl should have a colectomy. Two other patients in this series acquired the disease in the first year of life. Prior to the appearance of the disease in these two infants we were not aware that it ever occurred at such an early age. In both instances a very careful study was made to see if there were not some other etiologic factor and in neither case was any found. Both infants had very careful medical care and ileostomy was resorted to only when a fatal outcome seemed imminent. In both instances great difficulty was experienced in maintaining adequate body fluids, both before and after ileostomy. The continuous introduction of saline solution intravenously proved to be very helpful and was continued for more than a week in both patients. The older of the two, who was seven months when the ileostomy was performed, was in good condition at the age of two years except for a slight rectal stricture which dilated readily. We believe this ileostomy can be closed soon. The younger of the two infants has had the ileostomy for seven months and is in good health at the present time. It is still too early to hazard a guess about the closure of the artificial opening.

There have been 7 deaths in this series of 26 cases, some directly attributable to the disease or its treatment and some of doubtful connection. One case has already been mentioned, the boy who did well for two years and then acquired a volvulus of the jejunum and died of intestinal obstruction. Another boy of thirteen who had the ileostomy performed in the seventh year of the disease, did exceptionally well for six months afterward. He had gained 40 pounds in weight when he developed carcinoma of the transverse colon, from which he died. A girl of nine years died of multiple perforations of the colon and peritonitis a week after she had the ileostomy performed. A boy nine years old who had had the disease over three years, died of perforation one month after ileostomy had been done, and another who had been followed medically at the Children's Hospital, died a few days after an ileostomy had been performed in another hospital. One patient who had done well for two years after the ileostomy, had a streptococcus infection of the wound following the operation for closure, and died, it was believed, of a streptococcus peritonitis. The

seventh patient died following an ileostomy and was found to have an ileitis as well as chronic ulcerative colitis at the postmortem examination.

Impressions.—It is doubtful whether conclusions are justified from so small a series of cases, but we have several definite impressions.

1. The cause of the disease is still unknown.
2. Diagnosis of idiopathic or chronic ulcerative colitis without careful bacteriologic, x-ray, and proctoscopic examinations is not warranted.
3. The disease has varying degrees of severity.
4. We regard the idea expressed by McKittrick and Miller that ileostomy should be considered a permanent condition, as slightly too pessimistic to apply to our age group.
5. Ileostomy is at times a life-saving procedure and is followed by rapid and lasting improvement in symptoms.
6. We believe ileostomy should be performed before too much structural change has taken place, if we are to avoid the artificial opening being permanent.

CLINIC OF DR. CLARK W. HEATH

THE THORNDIKE MEMORIAL LABORATORY, SECOND AND
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY HOS-
PITAL AND THE DEPARTMENT OF MEDICINE, HARVARD
MEDICAL SCHOOL

THE CLINICAL SIGNIFICANCE OF PROBLEMS OF AB- SORPTION IN THE HUMAN GASTRO-INTESTINAL TRACT

It is becoming increasingly evident that diseases due to nutritional deficiency may occur even when the diet seems to be adequate. Materials valuable to the body may be lost, for example, by hemorrhage from any part of the body, or by loss through the kidneys owing to disease of these organs. During growth, pregnancy, and in other conditions such as fever or hyperthyroidism, in which increased demands are made upon the body stores for necessary materials, dietary deficiency disease may result if the increased demands are not met by an adequate supply of substance derived from the food. In such conditions as sepsis, cancer and dysfunction of certain organs, necessary material, though present in the body, may not be properly utilized. The diet, moreover, may be quite adequate for a normal person, but because of an insufficient secretory mechanism in the gastro-intestinal tract, substances may not be made available for the body. Castle has demonstrated how such a mechanism may be productive of Addisonian pernicious anemia. In this disease there is a deficiency of an enzyme-like substance in the gastric juice, the presence of which, in normal individuals, produces by the interaction with certain materials of the food a specific substance necessary for normal blood formation. Lastly, the diet may be adequate, but because of various gastro-intestinal abnormalities with or without diarrhea, food substances may not be absorbed and therefore not reach the body itself. Minot, Strauss and

Cobb¹ have summarized the trend of knowledge regarding these factors in deficiency disease as follows: "One must also recognize that dietary deficiencies can develop because of disorders of the gastro-intestinal tract. Necessary material may not be properly elaborated because of a lack of gastro-intestinal secretions, as occurs in pernicious anemia, or nutritious elements may be absorbed unsatisfactorily, leading to a state of deficiency exactly as if an insufficient amount of proper food had been ingested."

The study of the normal mechanism of intestinal absorption has been pursued intensively by physiologists for many years. Physicians, moreover, have been aware for a long time of the importance of absorption in various aspects of medicine, for example, in the principle of the administration of cathartics, or in the choice of giving medicinal substances parenterally rather than orally. The presence of good teeth for mastication, and adequate preparation of the food by cooking have been long recognized as important factors for the assimilation of food. It is only recently, however, that the influence of absorption upon the causation of disease has attracted interest. It is timely, therefore, to summarize our conceptions of the pathologic physiology of absorption, to indicate the position it takes in clinical medicine, and to outline methods of clinical study and of treatment.

The Mechanism of Intestinal Absorption.—"Absorption" refers to the transfer of substances across the membrane of the intestine, so that they are made available to the body as a whole. Ingested substances are, for all practical purposes, still outside the body until they have passed the intestinal barrier. The preparation of food substances for absorption by the action of the various secretions of the digestive organs is, of course, intimately linked with the process of absorption itself. It is therefore obvious that impairment of the gastro-intestinal secretory mechanism and the absorptive mechanism may be difficult to separate clinically, and it is reasonable not to attempt to differentiate them too dogmatically.

In order to approach the problem of intestinal absorption in its relation to disease it is necessary to consider the normal mechanism of absorption. There seem to be innumerable fac-

tors which have to do with the absorption of substances in the intestine. *The nature of the substance itself* is of importance: its concentration and mass, state of dispersion, hydrogen-ion concentration, lipoid solubility, surface tension, and then also such factors as the nature of accompanying substances and of the external secretions of the gastro-intestinal tract. *The character of the bowel wall* is to be considered: the surface area (to which the number of villi contribute), the mechanisms of segmentation and peristaltic movement, the intra-intestinal pressure, the movements of the villi, the permeability of the intestinal wall, the blood flow in the capillaries, the so-called "vital" selective ability of the lining cells. The subject has been reviewed in detail by Goldschmidt² and Magee,³ and one draws the general conclusion from their work that, although physicochemical laws, in particular those of osmosis, can explain only a part of the phenomena of absorption, the apparently selective ability of epithelial cells may eventually be explained as physicochemical knowledge progresses. The factors governing normal absorption in the intestine being so numerous, it can readily be seen how complex may be the physicochemical states which modify absorption when the intestine is altered pathologically.

Certain substances are absorbed more easily than others from the intestine. Iron and the materials potent in pernicious anemia and pellagra are substances which apparently are not absorbed with ease, as is suggested by the great discrepancy between effective dosage when these substances are given by the parenteral route as opposed to the oral route. It seems possible that vitamins are likewise absorbed with relative difficulty and that this may explain the development of syndromes associated with deficiencies of these substances when the intestinal mechanism is disturbed although the diet is complete.

Clinical Evidence of Malabsorption as a Cause of Disease.—Whereas there is abundant clinical evidence of disease which seems to be directly or indirectly the result of malabsorption, the concept is only with great difficulty amenable to scientific proof. One must first of all be assured that the dietary intake has been adequate. This evidence is frequently lacking, or is very difficult to obtain. Since disorders of the gastro-intestinal tract are accompanied almost invariably by

place in the bowel in the course of such diseases as sprue, pellagra, and Addisonian pernicious anemia. Cowgill¹⁵ considers that the presence of adequate amounts of vitamin B may be of great importance to the normal functioning of the intestinal tract. An indication of the effect of restricted diet is reflected by the recent studies of Miller and Rhoads.¹⁶ They fed a modified canine-black-tongue-producing diet to swine and produced oral mucous membrane lesions, achlorhydria and a loss of the antipernicious anemia activity of the gastric secretion together with a blood picture which resembled that of pernicious anemia.

Hasty conclusions are unwise in this difficult field. It does not seem illogical, however, to consider that a vicious circle is common in many of the chronic deficiency states. The vicious circle may be stated as follows: inadequate dietary intake of certain necessary substances leads to anatomical or physiological changes within the intestine and then to diminished absorption of necessary substances, which in turn lead to further disorder of the intestinal function. The factors of race, age, inheritance, changes of the glands of internal secretion, climate may all play a rôle in the etiology of particular kinds of gastro-intestinal disorders leading to deficiency disease. The exact part which they play is impossible to define at the present time.

Methods of Clinical Study of the Rate of Absorption.

—The conditions affecting the normal rate of absorption being so many and varied, it is impossible to draw far-reaching conclusions from any one method of testing the rate of absorption. Surgical operative measures, moreover, which are of great value in animal experimentation, are not open to the clinician, except by chance in rare cases. Nevertheless, certain methods of clinical study have been in use. Some of these methods are: the glucose tolerance test which has been used in cases of chronic diarrhea; the study of the motility of the bowel;¹⁷ the transference of weight to distant parts of the body after the ingestion of water;¹⁸ the physiological effects of ingested drugs; allergic skin reactions to ingested protein;¹⁹ and the rate of excretion of dyes in the urine.²⁰ Singer and Wechsler²¹ found that, when the galactose toler-

ance test was performed upon patients with anemia and achlorhydria, no galactose appeared in the urine.

The author, working with Fullerton²² studied a variety of cases in which it was thought that some disturbance of intestinal absorption might be present, including cases of achlorhydria with and without anemia, infections, cirrhosis of the liver, myxedema and scurvy. It was found that the ingestion of water and its excretion in the urine depended upon so many variable factors that it was not of value. The same was found true of the ingestion of glycine and the subsequent determinations of the amino-acid nitrogen content of the blood. Employing a method which has been used by Thienes and Hockett,²³ they administered 0.25 Gm. of potassium iodide in dilute solution and determined the time of the first appearance of iodine in the sputum. In normal individuals, iodine first appeared in the sputum in from ten to fifteen minutes. In most of the cases the time of the first appearance of iodine was delayed significantly. As the patients improved, the time of the first appearance shortened and approached or reached the normal time. The appearance time of iodine after the administration of potassium iodide intravenously, by means of which the influence of the intestine was avoided, was similar in normal subjects and patients. It was therefore believed that delay in the appearance of iodine in the sputum after the ingestion of potassium iodide was a rough measure of disturbance of intestinal absorption.

These methods of studying absorption may be classified as indirect and there are quite obvious objections to many of them. A new technic, which offers the possibility of studying the rate of absorption by a direct method in man has been presented by Miller and Abbott.²⁴ This technic, which makes use of multiple lumen tubes passed into any desired part of the gastro-intestinal tract seems to offer a distinct advantage over indirect methods. It cannot be considered of value for routine use but will undoubtedly help to unravel certain problems regarding human intestinal absorption.

Treatment of Disordered Intestinal Function Inhibiting Absorption.—The advantage to be gained by a good method of testing the rate of intestinal absorption would be not only to detect diminution of the absorption rate in dis-

place in the bowel in the course of such diseases as sprue, pellagra, and Addisonian pernicious anemia. Cowgill¹⁵ considers that the presence of adequate amounts of vitamin B may be of great importance to the normal functioning of the intestinal tract. An indication of the effect of restricted diet is reflected by the recent studies of Miller and Rhoads.¹⁶ They fed a modified canine-black-tongue-producing diet to swine and produced oral mucous membrane lesions, achlorhydria and a loss of the antipernicious anemia activity of the gastric secretion together with a blood picture which resembled that of pernicious anemia.

It cannot be considered of value for routine use but will undoubtedly help to unravel certain problems regarding human intestinal absorption.

Treatment of Disordered Intestinal Function Inhibiting Absorption.—The advantage to be gained by a good method of testing the rate of intestinal absorption would be not only to detect diminution of the absorption rate in dis-

orders of the intestine, but also to aid in evaluating methods of treatment when such conditions existed. Very little, however, is accurately known of this subject. Recovery of the papillae of the tongue, improvement in the appearance of the mucosa of the stomach, and improvement of the appetite have been observed in various sorts of anemia associated with dietary deficiency following therapy with iron or liver extract. Spies,²⁵ among other physicians, has observed healing of mouth lesions and control of diarrhea in the treatment of pellagra with large doses of liver extract parenterally. Improvement of lingual changes and of diarrhea in sprue by the parenteral administration of liver extract also have been noted.¹⁰ Such improvement is very likely associated with a definite return toward normal of the accompanying pathology or altered physiology of the intestine. Large doses of a deficient factor, if necessary parenterally, therefore, are indicated when disorder of the intestine is associated with nutritional deficiency. The aim should be to detect nutritional deficiency early and before permanent damage to the bowel results. By being alert, one may perhaps recognize subjects susceptible to such disorders of the gastro-intestinal tract which might lead to deficiency disease, and thus preventive measures could be applied which undoubtedly would accomplish the most. From our present knowledge, preventive measures would consist largely in the choice of an optimal diet adjusted nicely in respect to all its constituents, having in mind the health of the body as a whole and the gastro-intestinal tract in particular.

HYPERTHYROIDISM.

PREVENTION AND TREATMENT OF ENDEMIC GOITER AND ITS COMPLICATIONS

GEORGE CRILE AND GEORGE CRILE, JR.

IN certain parts of the country, such as in the region of the Great Lakes, endemic goiter is prevalent. The iodine in this region has been washed from the soil and has flowed from the lakes to the sea. Therefore, the iodine intake of the average person is very low, and although it usually is sufficient for ordinary requirements, it may at times of particular endocrine activity fall below the level of physiological necessity, and result in a relative iodine deficiency.

Thyroxin, the active agent of thyroid secretion, is 65 per cent iodine. When a deficiency of iodine in the diet is present, the thyroid gland finds itself in the position of a factory attempting to maintain its output during a famine of raw material. The gland rapidly utilizes its store of iodine-containing colloid and undergoes hypertrophy and hyperplasia in an attempt to keep up its production of thyroxin. Although subsequent involution to the colloid phase occurs, these changes produce permanent alterations of thyroid histology, lay the foundation for endemic goiter and often result in the development of adenomata with their attendant complications of hyperthyroidism, growth to deforming size, and development of malignant change.

The times of greatest physiological stress so far as the thyroid gland is concerned are (1) during pregnancy and (2) during puberty and adolescence. To a lesser degree, infancy and childhood are characterized by excessive metabolic demands, but puberty and pregnancy deserve particular consideration.

IODINE DEFICIENCY IN PREGNANCY

Since early times, the enlargement of the thyroid gland associated with pregnancy has been noted. The basal metabolic rate in normal pregnancy may be elevated, and this is not surprising in view of the known activities of the glands of internal secretion at this time.

The appearance of or enlargement of a goiter at the time of pregnancy is a common finding in the history of patients in regions where the iodine content of the soil and water is low and where endemic goiter is prevalent. One may readily understand this change when one realizes that pregnancy is a period of increased thyroid activity and hence of increased physiological demand for iodine. For these reasons, we believe that every pregnant woman, who lives in regions where endemic goiter is prevalent, should have the benefit of prophylactic maintenance doses of iodine.

Iodized salt, in the early years of its use, fell into some disrepute because of the relatively enormous and unphysiological quantities of iodine it contained. It was thought that in some instances these larger doses of iodine had induced hyperthyroidism in previously inactive adenomata. But at the present time, the common brands of iodized salt contain only 1 part per 5000 of iodine, and the daily intake of iodine by a person who lives in a region of endemic goiter and uses iodized salt is no greater than that of a person who lives by the sea and uses uniodized salt.

A 25 per cent solution of potassium iodide in doses of one minim once a week is the cheapest form in which prophylactic doses of iodine may be prescribed. If tablet form is preferred, one iodostarin tablet is taken each Sunday morning and this will insure an intake of 10 mg. of iodine a week. Since the total requirements for a year are certainly not over 100 mg., an ample supply is thus afforded. By thus supplying the physiological demands of pregnancy, not only is goiter in the mother prevented, but congenital goiter and cretinism in the child may be avoided.

IODINE DEFICIENCY IN PUBERTY AND ADOLESCENCE

Although an adequate intake of iodine should be afforded the growing child, it is doubly important that the adolescent child should have prophylactic doses of iodine. At puberty, the thyroid shares in the general endocrine awakening of the child; it enlarges, becomes more vascular, and if any iodine deficiency exists, the gland may undergo a rapid hypertrophy and hyperplasia. In the presence of such an iodine deficiency, the superior thyroid arteries pulsate forcibly, and the gland may become so vascular that a bruit can be detected, although the basal metabolic rate is normal and there is no clinical evidence of hyperthyroidism. The involution of such a gland to the colloid phase results in the typical adolescent goiter. The prophylaxis of such changes consists merely in the administration of iodine in the same form and doses as those prescribed for iodine deficiency during pregnancy. The treatment of the fully developed adolescent goiter is a separate problem which will be discussed later in conjunction with the other complications that may follow iodine deficiency.

DIAGNOSIS AND TREATMENT OF CREBINISM AND CHILDHOOD HYPOTHYROIDISM

True cretinism is a rare condition in this country, but textbooks have made everyone familiar with the clinical picture, of the mentally and physically retarded, pot-bellied, big-tongued cretin. Childhood hypothyroidism on the other hand, presents a diagnostic problem of considerable magnitude in that it must be differentiated from the pituitary dyscrasias, the skeletal maldevelopments (chondrodystrophies, etc.), and mental retardations as well as from dwarfism secondary to infectious or nutritional disorders.

The relationship between hypothyroidism in childhood and iodine deficiency is uncertain, but its treatment, like the treatment of cretinism, is by the use of desiccated thyroid and not by iodine. The basal metabolic rate is not a satisfactory diagnostic criterion in children, and of more clinical significance than the finding of a low metabolism is the presence of retarded

dentition and delayed epiphyseal development. The blood cholesterol is quite consistently high in the presence of hypothyroidism in childhood and is a most dependable diagnostic aid. Unfortunately, the determination of the blood iodine is of more value in the diagnosis of hyperthyroidism than of hypothyroidism.

The daily doses which are necessary to correct childhood hypothyroidism vary from 1 to 3 grains of U.S.P. thyroid and this should be adjusted in accordance with the clinical response of the patient and the response of the blood cholesterol. It is usually well to begin with small doses which may be increased gradually.

ADOLESCENT GOITER

Adolescent goiter can always be prevented, but rarely can it be cured by medical treatment. In some cases, if the changes have been present for a relatively short time, if the patient is in the early teens, and if adequate doses of iodine (such as a 25 per cent solution of potassium iodide in one minimum dose given twice a week or 2 tablets of iodostarin each week) are given and are supplemented by thyroid in doses up to $\frac{1}{2}$ grain daily when the basal metabolic rate is normal, or in quantities sufficient to correct any hypometabolism that may be present, a gradual diminution in the size of the gland may be noted. In older children, however, and particularly in those more than eighteen years of age, little regression can be expected and the most we can hope for is prevention of further enlargement. There is no reason to consider the surgical removal of a diffuse, adolescent goiter unless it is extremely large and the patient desires its removal for cosmetic reasons.

THE DIFFUSE ADENOMATOUS GOITER

In the goiter regions of Switzerland, Wegelin's autopsy studies¹ have shown that (1) in the younger groups, nearly 100 per cent of the thyroid glands which were examined showed the presence of diffuse goiters; (2) as age advanced, an increasing percentage of nodular goiters were found; and (3) in the oldest groups, 100 per cent of the goiters were of

the nodular type. These figures show that the development of adenomata in a goitrous gland is nearly certain to occur if the patient lives long enough for these changes to take place.

We know that the serious complications of goiter are (1) hyperthyroidism, (2) intrathoracic growth, (3) growth to excessive size, and (4) the development of malignant tumors. More than 90 per cent of all malignant epithelial tumors of the thyroid have their origin in preexisting adenomata (Graham).² Practically all intrathoracic goiters are adenomata which have grown downward into the thorax. Hyperthyroidism, aside from true Graves' disease, is nearly certain to be associated with an adenomatous type of gland. What steps are we justified in taking to avoid the development of these serious complications? In short, should the routine removal of all nodular goiters be recommended?

It is quite obvious that the removal of all nodular goiters would be utterly impractical. In the first place, the incidence of adenomatous goiter is extremely high and in some regions the majority of the population may be affected. In the second place, the type of adenomatosis which is present in these cases appears, as Reinhoff's³ studies have indicated, to be a physiological process of degeneration and regeneration and involves the entire gland. Therefore, even after a subtotal thyroidectomy had been performed, a certain amount of adenomatous tissue would remain. And lastly, experience has shown us that malignant change is a relatively rare finding in the diffuse adenomatous gland. Hyperthyroidism, moreover, can be treated safely and cured surgically after it has appeared, and a substernal goiter can likewise be removed with safety after its symptoms bring the patient to the physician. In this type of gland, therefore, prophylactic thyroidectomy is not recommended and our policy is that of careful observation.

The indications for prompt thyroidectomy are (1) enlargement of an adenoma in a patient over thirty-five years of age; (2) the development of hyperthyroidism; (3) pressure symptoms denoting intrathoracic extension or tracheal compression; and (4) for cosmetic reasons at the patient's request. The

removal of a large goiter is also indicated in the presence of symptoms such as fatigue, palpitation and dyspnea, which are perhaps the result of a combination of psychic and mechanical factors, as well as of the presence of a large, vascular bed which places excessive strain on the myocardium.

THE DISCRETE ADENOMA

A different problem is presented by the finding of a firm, circumscribed, discrete adenoma, particularly in a patient beyond middle age. Even if there is no evidence of hyperthyroidism, even if the adenoma is of relatively small size, and even if there had been no recent growth, its removal should be advised.

The discrete adenoma has certain clinical and pathological qualities of neoplasia which render its management a different problem from that of the diffuse adenomatous gland, and it is in this type of tumor that we believe malignant change is most commonly seen. At least 2 per cent of such adenomata are found by the pathologist to be malignant despite the fact that the diagnosis is not suspected before operation. For this reason, we believe discrete adenomata should be removed before the patient reaches the age of thirty-five years. The following case illustrates this point:

The patient was a married woman aged forty-two years who was first seen at the Cleveland Clinic in September, 1922, complaining of goiter. Physical examination showed a small nodular enlargement of the thyroid gland. Dr. Crile, Sr., who saw the patient in consultation, made a diagnosis of fetal adenoma of the thyroid and recommended thyroidectomy. The patient refused operation and was not seen again until nearly three years after the first examination.

In 1925 she returned to the clinic complaining of enlargement of the thyroid and of pain in the left side of the neck which radiated upward behind the ear. Examination showed a large, hard, fixed goiter, and a diagnosis of malignant adenoma of the thyroid was made. Complete removal of the tumor was impossible. x-Ray therapy was given and temporary improvement followed, but the tumor recurred. Over a five-year period, the recurrences were held in control by x-ray therapy, but finally in 1930, the tumor lost its radiosensitivity and a decompression operation for relief of dyspnea was performed. The pathologic report of the tissues removed was malignant adenoma. The patient died in December, 1930 as a result of tracheal invasion by the tumor.

Had operation been performed when first advised, it is highly probable that the adenoma had not as yet become malignant and that a permanent cure would have ensued.

There are 5 other cases in our series in which a diagnosis of benign goiter was made and in which operation was advised at the time of the original examination but was deferred. At operation, a malignant tumor was found in each case, and in the majority of these, the tumor was so extensive that complete removal was impossible.

CARCINOMA OF THE THYROID GLAND

Four per cent of all nodular thyroid glands which are removed surgically are found by the pathologist to contain malignant tumors, and in only 50 per cent of the cases in our series was malignancy suspected at the time of the clinical examination. Therefore, an unsuspected malignant tumor is present in 2 per cent of the cases of nodular goiter that come to operation.

The diagnosis of malignancy of the thyroid is made by observation of the hardness or of the fixation of the gland. The first of these two classical signs is present only when the tumor which originates within the gland has enlarged to such an extent that it begins to involve the palpable surfaces; fixation, moreover, occurs only after the tumor has extended through the capsule. In short, the diagnosis of malignancy of the thyroid gland is usually possible only after the disease has progressed beyond the stage of curability.

In substantiation of this statement, an examination of the case records of 100 malignant tumors of the thyroid gland shows that the permanent cures are more than three times as common in those cases in which the preoperative diagnosis of malignancy was not made as in those in which it was made before operation.⁴ Therefore, if we are to cure malignant tumors of the thyroid, we must take advantage of the earliest sign, *i. e.*, enlargement of a discrete adenoma and we must not wait for the classical signs of cancer to develop. An enlarging adenoma should be removed prophylactically just as a breast tumor

should be removed before the clinical signs of malignancy develop.

HYPERTHYROIDISM

The treatment of hyperthyroidism is subtotal thyroidectomy. Temporization with iodine medication or with *x*-ray therapy is particularly undesirable in the presence of a nodular type of goiter. If early operation is performed, the disability is shorter, the cure permanent and the safety is maximum. If operation is delayed, the condition of the patient becomes serious and operation, although affording the only hope of cure, may be rendered dangerous.

INTRATHORACIC GOITER

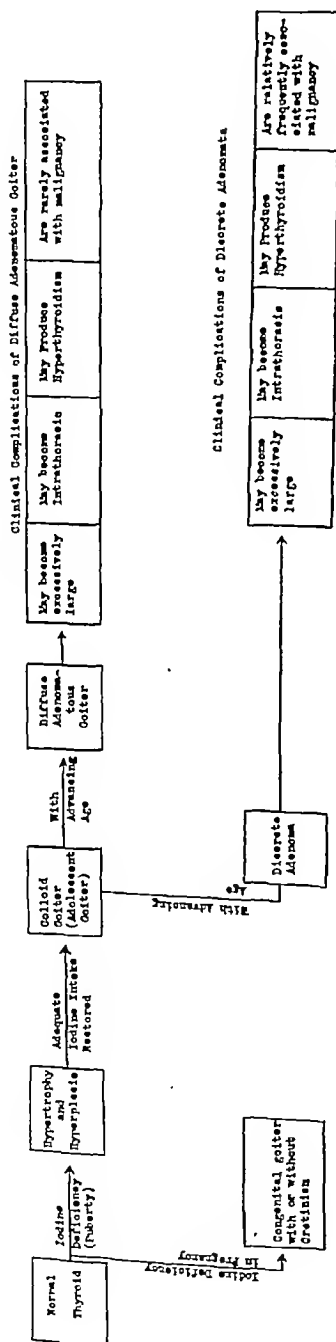

An intrathoracic goiter is rarely an aberrant gland but is almost always an adenoma which has grown downward or has been pushed downward into the thorax. As a rule, such an adenoma continues to grow slowly until finally, symptoms of tracheal or of venous obstruction occur. These symptoms usually become progressively more distressing to the patient until surgical relief finally is sought.

The removal of an intrathoracic goiter is not much more difficult than a simple thyroidectomy when the intrathoracic portion is small enough to be delivered through the outlet of the thoracic cage. The danger associated with this operation is encountered when the gland cannot be delivered except by morcellement. The necessity for such a relatively dangerous procedure could be obviated if the diagnosis were established by *x*-ray at the time when the symptoms first appeared, and if the surgical removal of the gland were not delayed.

CONCLUSIONS

Adenomata of the thyroid are the result of iodine deficiency. All intrathoracic goiters, all large goiters, more than 90 per cent of all malignant epithelial tumors of the thyroid gland, and 50 per cent of all the cases of hyperthyroidism have their origin in adenomata. Since a deficiency in iodine is easily preventable, the responsibility for the prevention of these dis-

THE CLINICAL EVOLUTION OF THYROID DISEASE AS RELATED TO IODINE DEFICIENCY

cases rests with the family physician. If the full cooperation of the patient could be obtained, and if all families were under the care of competent and well-trained physicians, the public could be taught the dangers of iodine deficiency and the incidence of serious thyroid disease could be reduced to at least 40 per cent of its present frequency.

It is important that the physician should know exactly what therapeutic results can be expected from medical treatment of thyroid disease, and that he should realize that in many instances, attempts at medical management result only in delay which jeopardizes the chances of surgical cure.

The diagram on page 1723 will emphasize the rôle of iodine deficiency in the production of diseases of the thyroid gland.

THE MANAGEMENT OF COMPLICATING FACTORS IN HYPERTHYROIDISM

A. CARLTON ERNSTENE

THE most effective treatment of hyperthyroidism consists of subtotal thyroidectomy during an iodine remission. In certain instances, however, the general condition of the patient and the severity of the disease may necessitate preliminary ligation of the superior thyroid arteries or limitation of the operation to the removal of one lobe of the thyroid at a time. Hyperthyroidism is complicated occasionally by the presence of other conditions. These complications do not affect the need for controlling the thyrotoxic state, but frequently they have an important influence upon preoperative and postoperative care and the decision as to the exact manner in which surgical treatment is to be carried out.

CARDIAC COMPLICATIONS

Dyspnea on exertion, tachycardia and palpitation are present to a certain degree in practically all thyrotoxic patients. In the absence of signs of congestive myocardial failure, however, these symptoms are not to be regarded as evidence of cardiac damage or of myocardial insufficiency, but rather as direct manifestations of the hyperthyroid state. They therefore require no treatment aside from the usual measures employed in preparing the patient for operation.

In certain individuals more important cardiovascular symptoms and signs are observed. Disturbances of heart rhythm occur in 10 or 15 per cent of all patients with hyperthyroidism. The most common abnormal rhythm is auricular fibrillation, although auricular flutter, auricular paroxysmal tachycardia and premature beats are observed at times. Auricular fibril-

lation may be present continually or in paroxysms of long or short duration and may occur in thyrotoxic individuals who have perfectly normal hearts. The arrhythmia is uncommon, however, in patients less than forty years of age, and in the great majority of persons above this age in whom it occurs, hypertension is present or the possibility of changes in the coronary arteries cannot be excluded. If the irregularity is present for a considerable length of time in untreated thyrotoxicosis, the myocardial reserve may be exhausted and signs of heart failure, such as pulmonary congestion, increased venous pressure, engorgement of the liver, dependent edema and orthopnea may develop. Myocardial failure occurs in only a small proportion of patients with hyperthyroidism, but in more than three fourths of the cases in which it does develop, uncontrolled auricular fibrillation has been present for some time. When congestive failure occurs in the presence of normal cardiac rhythm, the patient usually is over forty years of age and some complicating factor such as hypertension, arteriosclerosis or valvular heart disease is present. Myocardial failure with normal cardiac rhythm is extremely rare in young hyperthyroid subjects even though valvular heart disease is present.

An occasional patient with hyperthyroidism experiences attacks of angina pectoris. The first seizure of anginal pain usually occurs after the onset of active hyperthyroidism, although at times a history of earlier attacks is obtained. Hyperthyroidism *per se* probably is not capable of causing angina pectoris, and when patients with thyrotoxicosis experience attacks of anginal pain, the existence of some organic change in the heart, usually sclerosis of the coronary arteries, must be assumed.

The presence of cardiac arrhythmia, congestive myocardial failure or angina pectoris in patients with hyperthyroidism is not to be regarded as a contraindication for surgical treatment. In active thyrotoxicosis unaided medical management of these complications gives unsatisfactory end-results even though a period of temporary improvement may be obtained. Control

of the hyperthyroidism, on the other hand, usually results in complete or practically complete relief from all signs and symptoms referable to the cardiovascular system.

Careful preoperative treatment of the thyrotoxic patient presenting cardiac complications is of course of fundamental importance. As in persons with uncomplicated hyperthyroidism, the treatment consists of absolute rest in bed and the administration of a high calorie diet, Lugol's solution and sedatives. Large amounts of fluids are given except in the presence of myocardial failure. These measures alone frequently result in complete relief from all cardiovascular symptoms and in disappearance of the signs of mild congestive failure. Digitalis is administered only to patients with auricular fibrillation or myocardial failure. Additional therapeutic measures are seldom needed, although occasionally it may be necessary to administer a diuretic drug such as salyrgan. Usually the patient can be prepared for operation in from ten to fourteen days.

In approximately one half of all patients with hyperthyroidism and auricular fibrillation, the heart rhythm spontaneously becomes regular during the early part of convalescence following subtotal thyroidectomy; and in a majority of the remaining patients, normal rhythm can be restored by the oral administration of quinidine sulphate. Spontaneous reversion from auricular fibrillation to normal rhythm usually occurs within the first ten days after operation, and quinidine is employed only when the arrhythmia persists beyond this period. On the first day on which the drug is administered, 2 doses of 3 grains each are given two hours apart in order to determine that the patient is not hypersensitive to it. On the following day, 5 doses of 6 grains each are administered at intervals of two hours. The same amounts are given on subsequent days, but if normal rhythm is not re-established after one week, treatment is discontinued. Usually, however, the arrhythmia is terminated during the first or second day of full dosages. The drug is not administered to individuals known to be hypersensitive to quinine or to patients who have mitral stenosis. In the latter patients,

reversion to normal rhythm is attended by a definite risk of serious accident due to embolism.

The development of auricular fibrillation after operation is generally a complication of but little clinical importance. The irregularity usually lasts for less than forty-eight hours and rarely causes circulatory embarrassment. Normal rhythm almost always is reestablished spontaneously, and in all but a few cases no treatment is necessary. It has been our practice, however, to begin gradual digitalization with the onset of the arrhythmia so that the complete effect of the drug can be obtained more readily in the rare instances in which mild congestive failure does develop. If the arrhythmia should persist for more than ten days, quinidine may be used to restore normal rhythm.

DIABETES MELLITUS

Alimentary hyperglycemia and glycosuria occur not infrequently in patients with hyperthyroidism and are of no importance. One should make certain in each instance, however, that diabetes mellitus is not present. The differentiation can be made by measurements of the blood sugar content two hours after a meal or by the glucose tolerance test.

Diabetes mellitus is found to be present in approximately 2 per cent of all patients with hyperthyroidism. Although the presence of this condition frequently is not discovered until after the onset of hyperthyroidism, it is generally accepted that hyperthyroidism is not a direct cause of diabetes. Hyperthyroidism, however, causes a decided increase in the severity of preexistent diabetes, and it is probable that the development of frank diabetes *after* the onset of hyperthyroidism is due entirely to accentuation of a latent or previously unrecognized diabetic state.

The preoperative treatment of patients with hyperthyroidism and diabetes differs from the management of uncomplicated thyrotoxicosis only in that the diabetic patient frequently must be given rather large doses of insulin in order to accommodate the customary high calorie diet. Carbohydrates usu-

ally are given in amounts of 150 Gm. or more daily. Measurements of the blood sugar content should be made before each meal. Patients with hyperthyroidism and diabetes are more susceptible to hypoglycemia than are individuals with uncomplicated diabetes, and a close watch therefore must be kept for symptoms of this condition. It is important to bear in mind in this connection that, as an iodine remission is established, carbohydrate tolerance improves, and the dosage of insulin usually must be reduced. During the first few days after operation, it is often necessary to increase the dosage of insulin once more; after this, progressive improvement in the diabetic state generally occurs, and in many patients the use of insulin can be discontinued entirely within a relatively short time.

ARTHRITIS

A rather rare complication of hyperthyroidism consists in the development of a condition similar in all respects to idiopathic rheumatoid arthritis. The shoulders and the joints of the fingers are most commonly affected, although at times there may be involvement of practically all joints of the body. Examination reveals thickening of the periarticular tissues with local tenderness and limitation of movement which at times may be extreme. In advanced cases, flexion deformities and varying degrees of muscle atrophy develop. Roentgen examination fails to reveal gross bone or joint changes except for the presence of atrophy.

Physiotherapy and other therapeutic measures commonly employed in rheumatoid arthritis have no appreciable effect upon the arthritis which develops during hyperthyroidism. The induction of a remission in the thyrotoxic state by the administration of iodine also fails to improve the condition of the joints appreciably, and surgical measures such as ligation of the superior thyroid arteries or lobectomy, which only partially control the hyperthyroidism, likewise are of little or no benefit. Subtotal thyroidectomy after the usual preoperative management is followed, however, by prompt improvement. Within forty-eight hours after the operation there is frequently

a decided increase in the range of painless movement in the involved joints, and subsequently a majority of the patients experience gradual but eventually complete or practically complete recovery from the joint manifestations.

In persons in whom rheumatoid arthritis is present prior to the onset of hyperthyroidism, the joint symptoms usually are increased by the development of thyrotoxicosis and are benefited by subtotal thyroidectomy.

PSYCHOSES AND PSYCHONEUROSES

Hyperthyroidism is complicated at times by the development of definite psychotic states. Usually, in such instances, the thyrotoxicosis is quite severe, although exceptions to this are encountered. The most common psychosis is a toxic delirious mania but occasionally a schizophrenic state occurs. In other patients, severe psychoneuroses without frank psychoses develop during hyperthyroidism. It is probable that the constitution and temperament of the individual are important factors in determining the type of mental disturbance to be precipitated by thyrotoxicosis.

The prognosis in patients who present psychotic or severe psychoneurotic manifestations during hyperthyroidism is always unsatisfactory. Surgery of any kind usually is inadvisable so long as active symptoms are present, because even ligation of one superior thyroid artery may result in a serious increase in the severity of the symptoms and the development of a "hyperthyroid crisis." Roentgen-ray therapy also is contraindicated since it almost invariably increases rather than ameliorates the symptoms. It has been our experience that the most satisfactory course of treatment consists of carrying out the usual preoperative measures, for a period of months if necessary, until the mental symptoms subside. The patient should be kept at absolute rest in bed, sedatives should be employed freely, and large amounts of fluid should be given. Lugol's solution should be given in somewhat smaller amounts than are customary in uncomplicated hyperthyroidism—a daily dose of 5 minims is sufficient. Blood transfusions often are

of help in the severe cases. Even after the mental symptoms have been controlled, operation is attended by a definitely increased risk. Postoperative crises are common and are liable to be attended by a return of the psychotic or psychoneurotic manifestations. It is usually advisable, therefore, to carry out the operative procedures in stages, beginning frequently with preliminary ligation of the superior thyroid arteries. Postoperative management is of even more importance than in patients with uncomplicated hyperthyroidism. The patient should be placed in an oxygen tent immediately, sedatives should be given as necessary, and the intake of fluids should not be less than 3000 cc. per day. Physiologic solution of sodium chloride should be administered by hypodermoclysis in amounts sufficient to keep the total fluid intake at this level. Lugol's solution should be continued for several days. A rise in temperature to above 102° F. is combated by the application of ice bags or ice packs. Transfusion should be performed upon the first appearance of mental symptoms.

PULMONARY TUBERCULOSIS

Pulmonary tuberculosis is rarely encountered in patients with hyperthyroidism, and when the two diseases do occur together, the pulmonary condition usually runs a mild course. In these patients, active pulmonary tuberculosis antedates the onset of hyperthyroidism and does not appear to be adversely affected by the development of the thyrotoxic state. The treatment of hyperthyroidism in individuals with tuberculosis is the same as in patients with uncomplicated thyrotoxicosis.

PREGNANCY

During the latter part of normal pregnancy, a slight elevation in the basal metabolic rate usually develops, but rarely does this amount to an increase of more than 20 per cent. The rise is not accompanied by symptoms or signs of hyperthyroidism and is of no clinical significance. The rate returns to normal within a few days after delivery.

The development of active hyperthyroidism is an unusual

complication of pregnancy, but the fact that the patient is pregnant does not alter the principles of treatment of the thyrotoxicosis. Ideal treatment consists of subtotal thyroidectomy during an iodine remission. The course of gestation is seldom affected by the operation, and there is no need for terminating pregnancy as a preoperative measure.

SUMMARY

With the exception of the psychoses and severe psychoneurotic states, the complications which have been considered seldom affect the prognosis of hyperthyroidism to an important degree. Careful attention to details is necessary during the period of preparation for operation, and in certain instances the period of preoperative treatment must be prolonged beyond the time required in uncomplicated cases. Surgical treatment occasionally must be carried out in stages, and in patients with certain cardiac disturbances, diabetes mellitus or mental symptoms, extra precautions must be taken during the early postoperative period. Careful planning along these lines has resulted in a considerable reduction in the mortality rate of hyperthyroidism and, in this respect, is to be rated second in importance only to the routine preoperative use of iodine.

ATYPICAL HYPERTHYROIDISM

E. PERRY McCULLAGH

THE differential diagnosis of hyperthyroidism is usually considered from two widely divergent points of view. On the one hand are cases in which hyperthyroidism does not exist, but the disease is simulated by other conditions such as neuro-circulatory asthenia, the neuroses of the menopause, weight loss of obscure origin or at times by elevated basal metabolic rates of nonthyroid origin.¹ On the other hand are those cases in which hyperthyroidism *does* exist, but for various reasons may simulate other diseases. The first group assumes clinical importance, since the wrong diagnosis may lead to unnecessary thyroid surgery, while the second group is perhaps more important, since a failure to arrive at the correct diagnosis may deprive the patient of the benefits of such surgery as may be necessary to preserve health or life. The second group will be considered here.

One outstanding and simple reason why atypical hyperthyroidism may remain undiagnosed is that the condition is not suspected or not considered seriously enough in the differential diagnosis. The importance of this simple fact is apparent when we consider that the majority of cases of hyperthyroidism of clinical importance are associated with an elevated basal metabolic rate. However, since the basal metabolic rate is not ordinarily determined unless a metabolic or endocrine disorder is suspected, it remains important that we bear in mind the types of cases in which we may be misled. Neither is the basal metabolic rate always elevated, so that in questionable cases we should be prepared to depend entirely upon clinical evidence.

Cases of atypical hyperthyroidism may be considered in three main groups:

I. Hyperthyroidism in which symptoms and signs relating to one system are unusually prominent, thus producing a clinical picture which simulates a disease of a single system.

II. Hyperthyroidism in which one or more of the commonest symptoms or signs are lacking.

III. Hyperthyroidism complicated by another condition which dominates the clinical picture.

I. HYPERTHYROIDISM WITH SIGNS RELATED CHIEFLY TO ONE SYSTEM

(A) **Cardiovascular System.**—The most common type of patient with atypical hyperthyroidism in this group is the so-called "thyrocardiac." These patients are usually women over forty years of age who have a visible or palpable nodular goiter, but in a few cases there may be no palpable thyroid enlargement. The history will usually disclose symptoms of mild cardiac decompensation which have been present for a period of months or perhaps years. Repeated attacks of fibrillation may have occurred, a few cases of flutter have been reported,² cases are seen which may masquerade for long periods of time as myocardial degeneration or hypertensive heart disease, and a diagnosis of mitral stenosis may have been made. Not infrequently, a middle-aged patient, usually with a goiter, will present herself showing all the evidences of cardiac decompensation which is unassociated with any other signs, and at first, the presence of hyperthyroidism may not be suggested. As in mitral stenosis, the cardiac dulness is increased to the left, the pulse may be somewhat rapid at rest, auricular fibrillation may occur, the sounds usually will be loud and snapping, a thrill or vibration may be felt at the apex, and a systolic murmur often can be heard at the apex, the base, or both; unlike mitral stenosis, however, no diastolic murmur is found.

In some cases, a low serum protein which is apparently closely associated in itself with long-standing hyperthyroidism³ may aggravate a tendency to edema. In almost all instances

of this sort of hyperthyroidism persistently high basal metabolic rates can be found. The response to iodine medication in such cases is not always convincing. Even when the decompensation is severe enough to necessitate that the thyroidectomy be performed in stages, entirely under local anesthesia and with the patient in the sitting position, the results will often be extremely gratifying. In the light of recent advances in our knowledge regarding the value of complete thyroidectomy in cardiac disorders of nonthyroid origin, one is forced to question whether in all the patients who formerly were improved following thyroidectomy, the cardiac damage was due entirely to thyroid disease. In some of these cases, factors such as arteriosclerosis or other impairment of the myocardial strength may have played a part, although in most instances, as stated above, a basal metabolic rate of plus 30 per cent or above argues strongly in favor of thyroid disease as the chief etiologic agent. Though the clinical conception of the thyrocardiac is undoubtedly useful, it should be remembered that present evidence favors the view that permanent organic damage does not occur to the heart as a result of thyroid disease alone, so that even in the case of severe cardiac failure from thyroid disease, if the heart is relieved of its burden of excessive work it may assume complete normality of function.

Occasionally an individual past forty years of age may be seen who has an adenoma of the thyroid associated with tachycardia. The metabolic rate may be slightly, if at all, elevated, and other evidences of hyperthyroidism may be almost completely absent. When other causes of tachycardia can be excluded, removal of the adenoma may allow the heart rate to return to normal.

(B) **Neuromuscular System.**—The neuromuscular system may produce practically the only signs of hyperthyroidism. A man forty-five years of age has recently come to our attention in whom muscular weakness and severe, coarse, visible tremor of the limbs and entire trunk were the chief symptoms. Because of weight loss of 10 pounds in eleven months associated with a good appetite, hyperthyroidism had been

questioned and the basal metabolic rates were plus 37 per cent, plus 29 per cent and plus 18 per cent. There was, however, only questionable thyroid enlargement and with the exception of six preoperative days in the hospital, the pulse rate had been below 90. Because of the extremely marked tremor, the relatively normal thyroid size and pulse rate, and in spite of the elevated metabolic rate, the surgeons in charge were about to refuse the patient operation. Further observation showed that he was losing weight on a diet of 2500 calories per day while at rest in bed, and it appeared to some of us that the facial expression of the patient, his restlessness and mental irritability, his moist warm skin and loud snapping heart sounds were sufficient to warrant the diagnosis of hyperthyroidism. This opinion was corroborated by prompt recovery following partial thyroidectomy.

Elderly patients with adenomatous goiters or occasionally with little or no thyroid enlargement may be seen at times with a chronic low-grade hyperthyroidism of a type similar to that described above. The facial appearance may be more suggestive of fatigue than of stimulation (the so-called "apathetic hyperthyroidism"⁴) and most of the evidences of hyperthyroidism may be lacking. Muscular weakness and gradual progressive weight loss may be the only symptoms of consequence. Here again, the chief concern is the serious consideration of the possible presence of hyperthyroidism. A careful survey of symptoms, signs, and laboratory data, special tests or trial on iodine will seldom fail to lead to the correct diagnosis. Lahey⁵ has warned against the tendency to high postoperative mortality in such cases and suggests the frequent use of the two-stage operation, a single lobectomy being done on each occasion a few weeks apart.

(C) **Disorders of Metabolism.**—Weight loss is seldom if ever the only presenting evidence of hyperthyroidism, but it may be the most evident sign. If there is no obvious cause for weight loss and the diabetes can be excluded, hyperthyroidism deserves careful consideration.

(D) **Ophthalmic Disorders.**—Eye signs may be the only

presenting evidence of hyperthyroidism for some months, but this apparently is a rare occurrence. In one instance, a woman complained only of widening of the left palpebral fissure. No other evidence of hyperthyroidism could be demonstrated during two and a half months of observation, at the end of which time visible and measurable evidences of involvement of the opposite palpebral fissure began to be apparent. The basal metabolic rate at this time was plus 15 per cent. Although there was only questionable enlargement of the thyroid gland, thyroidectomy was advised and performed, following which the eye signs disappeared.

(E) **Gastro-intestinal System.**—Diarrhea occurs in the course of hyperthyroidism in some cases. Shirer⁶ demonstrated that hypermotility of the gastro-intestinal tract was present in 92.5 per cent of 42 cases studied by x-ray, the presence of hypermotility being based on the advance of the head of the barium meal to the cecum or beyond in three hours. Diarrhea in the presence of hyperthyroidism has been seen in this clinic less frequently recently than it was previous to six or eight years ago, and my associates cannot recall a single case in which gastro-intestinal symptoms were the only clinical evidence of hyperthyroidism.

II. HYPERTHYROIDISM IN WHICH ONE OR MORE OF THE COMMONEST SYMPTOMS OR SIGNS ARE LACKING

Some of the most striking features of hyperthyroidism such as tachycardia, goiter, hypermetabolism and weight loss may be absent in some cases.

When tachycardia and elevation of the basal metabolic rate are not found, it may be difficult to know whether their absence is an unusual feature in the particular case in question or whether it is simply an evidence of a natural or induced remission of hyperthyroidism. Continued observation may supply the answer, but such observation is not always feasible.

A normal pulse rate in the presence of active hyperthyroidism is an uncommon finding, and I doubt whether statistics would be of real value. I have not seen it in young people

except in cases of remission and the striking instances which I have observed have been in men past middle age. In some instances, the tachycardia observed while the patient is being examined may disappear after one day in the hospital, so that one does not see the typical pulse curve of hyperthyroidism, which following treatment gradually falls within from one to three weeks. Occasionally, a pulse rate which was about 70 preoperatively, will be reduced to perhaps 50 following the disappearance of hyperthyroidism.

The thyroid gland may not be visibly or palpably enlarged in the presence of hyperthyroidism.⁷ If other features of the disease are present, this fact should not deter one from making the diagnosis and applying all the usual methods of therapy.

Most writers agree that hyperthyroidism does exist without an elevated basal metabolic rate even apart from such an occurrence in cases of remission. It occurs most commonly in patients with nodular goiter and therefore in women past middle age. In such instances, it appears that a chronic low-grade hyperthyroidism which has been present for a long time may become burned out so far as a metabolic response is concerned and yet other clinical evidences of the disease may remain. We agree with Morris⁸ that the metabolic rate should be disregarded entirely where there is clinical evidence of thyrotoxicosis and when a goiter is present. If neither goiter nor elevated metabolic rate are present, extreme caution is necessary in arriving at a diagnosis of thyroid hyperactivity.

It should be borne in mind that symptoms of hyperthyroidism and hypothyroidism may be peculiarly intermingled in some cases; localized myxedema in individuals with hyperthyroidism has never been adequately explained. In one of my cases, remissions in the course of hyperthyroidism were so complete as to be associated with basal metabolic rates of minus 25 per cent and clinical evidence of hypothyroidism requiring the use of desiccated thyroid. This patient later had definitely elevated basal metabolic rates and all the clinical signs of hyperthyroidism again. It is possible that such extreme remissions may explain some of the cases in which the

oral use of thyroid preparations is purported to have caused hyperthyroidism.

In all cases where the basal metabolic rate is normal, the diagnosis of hyperthyroidism must be made with caution. The final results of operation in such instances suggest that diagnostic errors are frequent. Gordon and Graham⁹ report 71 cases of hyperthyroidism associated with normal basal metabolic rates, 17 of which were associated with diffuse goiters and 54 with nodular goiters. Operative cures were secured in only 53 per cent of the first group and 66 per cent of the second with improvement in 35 per cent and 18 per cent respectively.

Persistent weight gain in the presence of active hyperthyroidism may occasionally be seen. This occurs at times in young individuals in whom a voracious appetite more than compensates for the tendency to weight loss incurred by elevation of metabolic rates. As a rule, the diagnosis in such instances is clear.

III. HYPERTHYROIDISM COMPLICATED BY ANOTHER CONDITION WHICH DOMINATES THE CLINICAL PICTURE

Neurocirculatory asthenia is the one condition which perhaps is mistaken most frequently for hyperthyroidism. It occurs in young individuals and is usually marked by the symptoms of nervousness, fatigue and palpitation. Goiter is not an infrequent accompaniment. In neurocirculatory asthenia, the features which ordinarily serve to distinguish the condition from hyperthyroidism are cold, wet, sometimes cyanotic hands and feet, the relatively great variability in the pulse rate, more pronounced signs of sympathetic nervous instability than are usually present in hyperthyroidism, and the general neurotic attitude of the individual. Even the basal metabolic rate may be misleading, at least temporarily, since it tends to vary in the same way as the pulse rate, being perhaps 15 or 18 per cent above normal on one or more occasions. Mild hyperthyroidism supervening in such an individual

may be completely masked and may defy careful scrutiny. A gradual change in facial expression, persistent elevation of the systolic pressure and persistent tachycardia at rest and on repeated observations may serve to put the clinician on his guard. Persistent elevation of the basal metabolic rate above plus 20 per cent or the repeated finding of blood iodine levels of from 15 to 18 micrograms per 100 cc. are useful corroborative evidences. In these cases, operative interference may give only partial symptomatic relief, the hyperthyroidism disappearing, but the neurocirculatory asthenia remaining.

Since arterial hypertension may simulate hyperthyroidism its presence may also "mask" hyperthyroidism. The hypertensive patient may have a flushed face and a mild tachycardia may be highly suggestive of thyroid disease and although an elevated diastolic pressure is not caused by hyperthyroidism neither does its presence exclude the disease. The persistently elevated basal metabolic rate present in some cases of hypertension has not, I think, been adequately explained. If after careful observation and therapeutic trial on iodine there is still real cause for doubt, it may be wisest to err (especially in the presence of goiter) on the side of hyperthyroidism and allow the patient what benefit can be obtained from operation.

Organic heart disease may produce evidence which may direct the clinician's attention away from hyperthyroidism. If a goiter is present and even in the face of decompensation and obvious organic heart disease, hyperthyroidism deserves careful consideration. Here the basal metabolic rate and careful consideration of the possible presence of hyperthyroidism will serve to make the diagnosis clear and elimination of thyroid overactivity will give most gratifying results in most instances.

Menopausal symptoms may overshadow a mild hyperthyroidism such as so often occurs in the case of the middle-aged woman. In all instances where goiter is present this possibility should be seriously considered, and if large doses of estrogenic substances give less relief than is usually seen, or leave a residue of symptoms, possibly of thyroid origin,

even greater suspicion is warranted. If the metabolic rate is persistently high and the blood iodine distinctly elevated, the diagnosis is clear. In case of doubt, it is wiser to advise the removal of an adenoma than to risk the effects of low-grade hyperthyroidism over a long period of time.

Since diabetes and goiter are both common, it is to be expected that their incidence should coincide somewhat. The frequency of association of the two diseases has never been adequately shown to be greater than would be expected on a basis of the rate of occurrence of either alone. When a diabetic presents himself with glycosuria which may appear adequate to explain his weakness, weight loss or even the nervous restlessness or mild tachycardia sometimes seen, it is easy to forget the possibility of hyperthyroidism. Again, especially when thyroid enlargement is present, hyperthyroidism should not be excluded from the diagnosis except after careful consideration. This is especially important since lowering of the metabolic rate may be followed by great improvement in the severity of the diabetes.

Hyperthyroidism commonly occurs in association with pituitary diseases, especially acromegaly and those clinical syndromes simulating the pituitary-adrenal syndrome or pituitary basophilism. When clinical features of such pituitary disease are present, thyroid abnormality should always be excluded.

DIAGNOSIS AND TREATMENT OF HYPOTHYROIDISM

C. L. HARTSOCK

IN spite of the fact that it practically always gives clinical clues that should cause its presence to be suspected, in spite of the fact that there is a simple laboratory test which should confirm or disprove this suspicion, and in spite of the fact that a specific therapy is available which will very quickly give undisputed proof of its presence, thyroid insufficiency still remains one of the most frequently overlooked causes of morbidity. There must be some simple reason why this disease, which responds so readily to treatment, should so often go unrecognized. The patient, anxious to be well, tells his history as honestly and completely as he knows how, while we physicians, zealous to cure the patient, make as complete an examination as in any other case. It is in this manner that the true diagnosis of most diseases is discovered; however, if the patient has hypothyroidism, he too frequently goes away from his physician with only a symptomatic diagnosis such as neurasthenia, nervous exhaustion, anemia, low blood pressure, constipation, etc.

I believe that the following factors are responsible for the difficulty which attends recognition of this disease:

1. The disease is much more prevalent than is generally supposed and it is the basic cause of many symptoms that often are attributed to local disturbances in the various systems of the body, rather than to a general cause.
2. The disease characteristically produces negative symptoms and signs rather than positive ones that call our attention to the presence of organic disease.

3. The onset is insidious. Frequently, it is present for years before the patient is even aware that he does not feel as well as he should.

4. The manifestations of the disease at different age periods vary greatly and the presenting symptoms may be referable to any system in the body so that it is difficult to associate them with one common etiological factor.

5. The textbooks have emphasized the advanced types of hypothyroidism and described some of the cardinal symptoms, but have neglected to mention many of the prodromal symptoms and signs which have been present for years before the characteristic picture develops. Oftentimes, a sufficient degree of thyroid insufficiency to bring out the characteristic picture is never developed, and it is these cases that are most frequently overlooked.

When I realized that I was overlooking this disease entirely too frequently, I quickly discovered that there was only one way to make certain that these cases would not escape recognition, and that was to exclude thyroid insufficiency as a factor in every case rather than to include it as a possibility only if some positive clue suggested its presence. As a result of this decision, exclusion has been carried to such an extent that a normal basal metabolic reading has been disregarded in many cases and the more accurate therapeutic test has been tried. This statement will immediately excite the usual criticism which is made when a person is particularly interested in any specific condition; namely, that he makes a diagnosis of the disease in which he is interested entirely too frequently and thereby overlooks other causes of the patient's disability. In my own case, it was not so much an interest in the disease that led me to adopt this method, but these measures were carried out purely as a means of better recognition of cases of hypothyroidism.

When thyroid insufficiency is present, it causes an incomplete oxidation in the metabolic processes of almost all, if not all, the cells of the body. Depending upon the use of the organs of which these cells are an integral part and upon the

amount of damage to the organ by previous stress, strain and disease, the first effects of the disturbed metabolism usually will be to manifest itself by symptoms referable to some particular system rather than to symptoms referable to the entire body, such as is seen in the more advanced cases. Many vague and puzzling symptoms which otherwise receive purely symptomatic treatment without much result, can be explained and cleared up on this basis.

The different systems of the body will be considered and some of the more pronounced disturbances that can be caused by thyroid insufficiency will be cited. It must be kept in mind that these symptoms and signs are the result of a purely metabolic disturbance and can of course be produced by conditions other than hypothyroidism.

Central Nervous System.—Somnolence is a symptom of severe thyroid insufficiency and when it is present the patient is usually in a myxedematous condition. Forgetfulness, lack of concentration and a tendency to procrastinate are also symptoms which appear in a late stage of the disease. Restlessness, nervousness and insomnia are more common in the mild cases. Chronic headache which recurs frequently is also a common symptom. These early symptoms are more the result of the general fatigue and hypotension than the direct results of the metabolic disturbance.

Ocular System.—Muscle errors which are due to fatigue of the ocular muscle are very common and these in turn may cause a host of vague secondary symptoms such as dizziness, headache, neuralgia, and many others that we frequently ascribe to neurasthenia. Exophoria which occurs toward the end of the day is the most frequent type of muscle imbalance.

Ear, Nose and Throat.—A slight edema of the membranes of the nose and throat may be secondary to hypothyroidism. Allergy, another cause for boggy membranes, usually is more pronounced when it is associated with hypothyroidism. We have observed a very interesting symptom complex which is a result of this edematous condition of the membranes. When the membranes near the orifice of the eustachian tube are

swollen, there is a tendency for the tube to close and the patient complains of the very annoying sensation in the ear which results from this closure. Rather typical of this type of closure of the tube is its tendency to occur and disappear, sometimes several times in the same day. The use of ephedrine and air inflation of the tube give only temporary relief, but adequate treatment with thyroid gives quick and permanent relief. Tinnitus is sometimes due to the same cause. Degeneration of the eighth nerve should be suspected of being due to a thyroid disorder. Swelling of the tongue and chronic hoarseness are late symptoms of myxedema.

Cardiovascular System.—Bradycardia should always suggest the presence of hypothyroidism but the pulse rate is an unreliable guide because in many cases it is normal or increased. Thyroid insufficiency is occasionally the sole explanation for myocardial weakness. A clue to this etiological factor is found in the low amplitude of the electrocardiographic tracing. Due to the increased cholesterol content of the blood in the presence of hypothyroidism, it may also be a factor in the production of arteriosclerosis, but no improvement is noted following treatment with thyroid, although in early cases it is possible that the progress might be arrested.

Dyspnea is entirely a secondary symptom, but that very peculiar type of dyspnea which is best described as sighing respiration is occasionally due to hypothyroidism; more frequently, however, it is due to an anxiety state.

Gastro-intestinal System.—Obstinate constipation as a result of an atonic colon is a characteristic symptom, but all types of indigestion due to fatigue of the gastro-intestinal tract may be caused or aggravated by hypothyroidism. I observed one very interesting case of sudden periodic vomiting in a young woman. No other explanation for her symptoms was ever found and because of other distinct signs of hypothyroidism and a very low basal metabolic rate, she was treated solely from this angle with complete relief from the vomiting. The explanation for this is not clear.

Achlorhydria seems to occur somewhat more frequently

in hypothyroidism but this is such a common finding in patients past middle age that coincidence would lessen the value of such statistics. Adequate therapy certainly does not cause a return of the hydrochloric acid.

Genito-urinary System.—One of the classical mistakes in diagnosis is mistaking a case of myxedema for nephritis because of large amounts of albumin in the urine. I observed such a case recently. The patient's symptoms were of twelve years' duration, and she had been consulting doctors almost continuously up until five years before our examination, when her physicians made a diagnosis of nephritis, gave up all hope for her cure and sent her home from the hospital to die. The patient ceased all medical aid or advice and peculiarly enough, her condition improved, but it was still the most advanced case of myxedema I ever saw. The basal metabolic rate was minus 41 per cent. Improvement on thyroid medication was, of course, startling.

Impotence and sterility both in the male and female should cause one to suspect hypothyroidism. In one case, a woman was unable to carry pregnancies to full term, but after the institution of thyroid therapy, she had two full-term, normal pregnancies.

Glandular System.—Polyglandular disturbances associated with hypothyroidism as a minor or secondary feature are very commonly found, but in many cases the entire glandular syndrome is improved by the use of thyroid therapy alone, and this is especially true in ovarian types of menstrual disorders. Great advances have been made in specific glandular substitution therapy but thyroid therapy still remains the most potent and specific. It still is of great value in the treatment of pituitary, thyroid, and ovarian types of polyglandular disorders in conjunction with other indicated hormonal therapy.

Skeletal and Muscular System.—Vague muscular aches and pains frequently have their origin in thyroid deficiency. Any tendency toward degenerative arthritis is hastened by a low metabolic state. The disturbance of skeletal growth is well exemplified in the cretin.

Hematopoietic System.—A mild hypochromic anemia without any other satisfactory explanation should excite a suspicion of thyroid insufficiency. The marked anemias which were thought to be due to myxedema and which simulate pernicious anemia probably also have some deficiency of the extrinsic or intrinsic factor of pernicious anemia.

Hair, Nails and Skin.—Dryness of the hair and skin, brittle and thick, coarse nails, falling hair and premature greying of the hair are very suggestive symptoms of this disease and sometimes give the earliest clues.

General Symptoms.—Obesity, both generalized and that localized around the pelvic and shoulder regions is the classical sign which usually directs attention to hypothyroidism; however, a fact which is not so generally known is that many thin individuals who never could gain weight begin to do so immediately when they follow well-regulated and observed treatment for mild thyroid insufficiency.

Localized and circumscribed swellings are frequently of myxedematous origin. Swelling of the extremities with changes of temperature or prolonged dependency suggest an early myxedematous state.

Intolerance of cold and a subnormal temperature is usually found, but several cases of chronic pyrexia have been reported that responded to no therapy other than thyroid. Lack of thirst and hypohidrosis are further suggestive general symptoms.

Many other vague symptoms could be cited that are secondary to the chronic fatigue, decreased cellular function and inadequate oxidation of thyroid insufficiency, but this would only serve to make the picture confusing. If the more important symptoms mentioned above are kept in mind, one or more will stand out prominently enough to cause the condition to be suspected and recognized.

The variation in the picture of hypothyroidism in the different age groups—children, young adults, and mature adults, is also confusing. Severe hypothyroidism in the child causes the typical picture of cretinism which presents such a

classical picture and has been so adequately described in every textbook that no further discussion is necessary here. Very little is known, however, about mild degrees of hypothyroidism in children. The difficulty of obtaining satisfactory metabolic studies, the normal variability of children's weight, growth, development and intelligence, and the fear of using thyroid preparations in the growing child has presented many obstacles to the investigation of this problem. Undoubtedly, many of the subnormal childhood conditions about which the mother is much more concerned than the physician eventually will be shown to be due to thyroid insufficiency. Diagnostic criteria are still so limited in this group at the present time that we must wait for further studies before we can attempt to recognize and treat the incipient states of hypothyroidism in children.

Severe hypothyroidism can be present in middle-aged patients with surprisingly few of the classical symptoms. It is in this group that the more bizarre symptoms of thyroid insufficiency which were mentioned above are seen. Patients in the older group usually present at least a few of the symptoms suggestive of the clinical picture of myxedema. Rarely do they show them all.

Differential Diagnosis.—Many conditions must be taken into consideration in the differential diagnosis of hypothyroidism but two are especially confusing. The symptomatology of the recently described clinical syndrome, achlorhydric anemia or idiopathic hypochromic anemia, frequently suggests hypothyroidism and unless laboratory studies clearly differentiate the two, it is sometimes necessary to determine whether iron or thyroid replacement therapy is the more specific before the true diagnosis can be determined. Some cases are apparently a combination of both conditions and these do better when both medications are used.

Depressed and exhausted states are especially confusing because the basal metabolic rate is also very low in these conditions and it is difficult to tell whether the exhaustion is the result of the low metabolism or vice versa. It is in this type

of case that the therapeutic trial is of great value in the differential diagnosis. Blood cholesterol studies should be made routinely as a differential diagnostic measure because an increase in this substance in the blood is highly suggestive of the presence of hypothyroidism. Whether the clinical picture, the basal metabolic rate and blood cholesterol definitely point to, or only suggest the presence of thyroid insufficiency, the final answer depends upon the ability of the patient to tolerate the specific substance of the thyroid gland.

Treatment.—If the patient has hypothyroidism, he should tolerate the replacement of an amount of thyroid equal to that which is deficient, and there should be a concurrent improvement of the condition, especially in the subjective symptoms. Unless objective signs are outstanding, they respond slower than the subjective symptoms. Similarly, if the diagnosis is erroneous and the patient's symptoms are not the result of hypothyroidism, unpleasant subjective symptoms will soon result from overstimulation of the thyroid, and the treatment should be discontinued or tried again with very small dosage.

Many patients and also many physicians are very reluctant to use thyroid substance because of their fear of inducing hyperthyroidism. While it is true that practically all the toxic symptoms of hyperthyroidism can be reproduced by administering the active principle of the thyroid gland, these symptoms promptly subside when the medication is withdrawn, and I have never seen permanent hyperthyroidism induced by the use of the active hormone. A word of caution to the patient and frequent observation offset all dangers attached to the use of thyroid substance.

In a given case where it is decided to use thyroid treatment, the evidence for the disease may either be conclusive or only suspicious. In the former, any other treatment that the patient may need can be prescribed at the time the original prescription for thyroid is given, but in the suspicious cases, it is advisable to have several weeks' observation when thyroid therapy alone is used. This serves to offset the faulty

observation that improvement was due to the thyroid medication when it may have been due to the other treatment. Psychic improvement which comes so frequently for a few weeks after a visit to a confidence-inspiring physician must also be discounted in judging the effects of a trial thyroid therapeutic test.

Once it has been determined that a deficiency in thyroid exists, the rules of treatment are very simple. It is advisable for the physician to experiment with various brands of thyroid products, finally choosing one that he finds potent and then becoming familiar with what results can be expected with various dosages. The potency of the various brands varies so much that it is difficult to stabilize the patient if the same brand is not used continuously throughout the treatment.

The physician should try to bring the patient's metabolism to normal and maintain it at that level. To accomplish this, the beginning dose should be estimated below the amount that will be thought necessary to bring the metabolic rate up to normal. If this dosage is tolerated satisfactorily, it can gradually be increased at intervals of several weeks until a normal metabolic rate is reached. This can be determined partly by clinical observation supplemented by an occasional test of the basal metabolic rate. When a normal level is reached, it is usually necessary to reduce the dosage slightly for a maintenance dose. Frequently at this point the physician does not impress upon the patient the fact that thyroid therapy is only replacement therapy and not curative therapy. This results in the patient believing he is now normal and discontinuing treatment, so that the former condition of hypothyroidism occurs again. Once a diabetic, always a diabetic, and that is also true of hypothyroidism. Changes in environmental circumstances and geographical locations may affect this statement somewhat but in general it is true. The hypothyroidism that so frequently follows subtotal thyroidectomy for hyperthyroidism differs in this regard from nonsurgical hypothyroidism. In these cases the hypothyroidism may last only a short time, but if it persists for as long as two years after the

thyroidectomy, it is usually permanent and demands constant treatment.

After the maintenance dose has been established, periodic checkings every three to six months are advisable. The thyroid insufficiency may be progressive and it may be necessary to increase the dosage from time to time. The insufficiency may remain stationary but other influences may necessitate a change in the dosage. This is particularly true during pregnancy, following illness and with changes of emotional states and geographical location.

In my experience, the basal metabolic rate does not give a very good indication of the amount of thyroid substance that will be necessary to bring the rate up to normal; therefore, the dosages should be worked out in each individual case by the trial and error method. Some patients who have severe myxedema and a very low reading will respond to moderate doses of thyroid substance, while others whose symptoms are rather vague and whose rates are not much below normal will require very large doses before any benefit is derived. This appears illogical, and it may be possible that in some cases there is some difficulty with absorption from the gastrointestinal tract.

Owing to the great variation in the potency of thyroid preparations, it is difficult to discuss exact dosages unless one speaks in terms of thyroxin, which is rarely used on account of the expense. I rarely start treatment on less than a grain of thyroid extract (American standard) believing that if the patient does not tolerate this dosage, hypothyroidism does not play much part in the production of symptoms. However, in some of the polyglandular syndromes where other glandular preparations are being used also, smaller doses of thyroid may be combined with these to give the best results.

It is better to advise that thyroid medication should not be taken after midafternoon. If the medication is given after the evening meal, it frequently causes difficulty in getting to sleep and some palpitation of the heart when the patient first lies down. This rule does not apply if the patient's occupa-

tion or social life is such that his activities are greatest in the evening.

A slight overstimulation is likely to occur for an hour or so after thyroid medication is taken, especially following exercise, emotional excitement or lying down. This temporary excitement should not be enough indication to decrease or discontinue the dosage, but it is an indication that the patient is approaching a normal metabolism. Mild symptoms of excitement are sometimes annoying to patients however, and owing to the fact that the thyroid hormone cannot be supplied artificially with the regularity of the normal thyroid, it is sometimes necessary to maintain a patient at a metabolic level slightly below normal. As the metabolism approaches normal, the patient's subjective sense of well-being will furnish a better guide to his true condition than trying to maintain an absolutely normal metabolic rate. The test, as it usually is done, is not accurate enough to be an index of absolute normality, and furthermore, it must be remembered that the normal rate for each individual is not the same, some being higher and some lower than the standard normal.

In conclusion, I would like to emphasize the high incidence of hypothyroidism, especially in the so-called "goiter section" of the Great Lakes Region. Hyperthyroidism has long been known to be very prevalent in this location, but the number of patients who suffer with hypothyroidism far exceeds those with hyperthyroidism. If the attention of physicians were attracted as easily to the negative character of the symptoms of hypothyroidism as it is to the positive symptoms of hyperthyroidism, there would be a remarkable decrease in the low-grade morbidity of the health of the community.

CLINICAL PROBLEMS ASSOCIATED WITH MALIGNANCY OF THE THYROID GLAND

ROBERT S. DINSMORE AND JAMES H. YANT

MALIGNANCY of the thyroid gland is a clinical diagnosis which is hard to make in the early stages of the disease at a time when surgery plus irradiation may offer a cure. Allen Graham¹ pointed out several years ago and as Robertson Ward² emphasized more recently, the incidence of malignancy of the thyroid is greater in those regions where goiter is endemic. Therefore, it is of the utmost importance for practitioners in these regions in which thyroid disease is endemic to make a very careful examination of patients with goiters with a view to ruling out the presence of malignancy.

A very satisfactory classification of malignancy of the thyroid both clinically and pathologically is that given by Graham, and the one upon which we shall base our discussion.

Two types of sarcoma are found: lymphosarcoma and spindle cell sarcoma. Some authorities question whether or not sarcoma ever arises in the thyroid gland, but Graham,¹ Pemberton³ and Shallow, Lemmon and Saleeby⁴ definitely recognize that such does occur, although comparatively rarely. This diagnosis has been made only four times in the course of pathological examinations of 40,000 thyroid glands at the Mayo Clinic, and it has been made in 25 of 20,000 microscopic examinations at the Cleveland Clinic. It is felt that lymphosarcoma probably arises in the lymphoid tissue present in the thyroid, and that spindle cell sarcoma apparently has its origin in the stroma of the thyroid, in the capsule, or in the cicatricial tissue present in adenoma. Sarcoma of the thyroid

usually involves both lobes. These patients give a history of short duration of the tumor and very rapid growth, and they may complain bitterly of choking. The entire organ is firm and fixed, the fixation being due to extension to the adjacent tissues and the mediastinum. Distant metastases are uncommon because the local growth is usually so rapid that there is a fatal termination before metastases are recognizable. However, occasionally there is an exception to this general rule such as in the case reported by Schreiner and Murphy,⁵ in which the patient is alive and well fifteen years after x-ray treatment, a palliative operation for relief of pressure having been done previously by Crile.

The malignant adenoma arises in a preexisting adenoma. Unfortunately, only about one half of these cases are diagnosed clinically. In a series of 84 cases of malignant adenoma reported by Dinsmore and Crile, Jr.,⁶ the diagnosis was made in one third of the cases and was considered as a possibility in 58 per cent. Only 6 of the patients in this latter group are now alive and without recurrence.

Therefore, the importance of the early recognition of this change cannot be stressed too much. This transformation should be suspected in a middle-aged patient complaining that a nodular goiter which has been present for years has recently commenced to enlarge. It is usually stated that change in size has taken place quite suddenly, although the growth may be relatively slow. Unfortunately, this may be the only sign which is suggestive of the carcinomatous change, and even then it may be too late for effective treatment, because the tumor may have metastasized to distant parts by way of the blood stream, even though the capsule of the adenoma has not been broken nor have the lymphatics been invaded. When this type of neoplasm is in its early stage, the patients usually have no symptoms. The carcinomatous change is usually limited to one lobe or even one adenomatous nodule, although other adenomata may be present. The malignant adenoma will have an increase in its consistency which may be detected by the palpating fingers. As the tumor increases in size, certain

she had always had a full neck, but was quite insistent that this tumor had appeared within the preceding three months.

Physical examination revealed a movable tumor which felt cystic, and gave the impression that there had been a hemorrhage into an adenomatous cyst.

At the time of operation, however, the tumor was found to be completely filled with neoplastic tissue and the pathological diagnosis was malignant adenoma.

A course of x-ray therapy was given, but the patient returned in three months with a recurrence in the incision line. This was removed and was found to have cells of the same type as those noted in the tumor previously removed. Another course of x-ray therapy was given.

The patient returned from time to time and was found to be rapidly losing weight. Roentgenograms of the chest, pelvis, spine and long bones were made, but with the exception of a suspicious lesion in the left humerus, no metastases were found. The patient became very much emaciated and it was felt that she must have generalized metastases which could not be located, and death occurred about eighteen months after the primary operation. Before death, a large hard tumor appeared on the side of the face. This apparently was in the parotid gland.

Scirrhus carcinoma is also very slow growing, but its occurrence is so infrequent and it is so inevitably fatal, that it does not merit a great deal of consideration in this discussion. The papillary carcinoma gradually increases in size, and as stated before, metastasis does not take place until the lesion has broken through its capsule, and then usually only the adjacent lymphatics and lymph nodes are involved. The other two malignant tumors which were discussed, sarcoma and carcinoma-sarcoma, are very rapidly growing lesions of the thyroid, and may cause a fatal outcome within a few months or even weeks.

More than 80 per cent of the carcinomata of the thyroid have their origin in adenoma. About 65 per cent of the epithelial malignancies of the thyroid are malignant adenomata. Papillary carcinoma composes about 13 per cent of the total number of malignancies in the series of cases at the Cleveland Clinic. There were 6 cases of scirrhus carcinoma and 5 of carcinoma-sarcoma.

Hyperthyroidism associated with exophthalmos is a rare occurrence in the presence of malignancy. At the Cleveland

comes more pronounced. The patient will then complain of hoarseness, stridor, dysphagia, and choking. These latter symptoms appear when compression and invasion involve the sheath of the laryngeal nerves, the esophagus, larynx and trachea. With progression of the disease there will be marked fixation of the gland and it will be very firm.

The time when these symptoms appear, of course, depends upon the rate of growth, which in turn is dependent to a great

Fig. 181.—Photograph showing size of tumor which had appeared within the preceding three months.

degree upon the type of malignancy present. The growth of the malignant adenoma is comparatively slow, but unfortunately this tumor may metastasize to distant parts relatively early. Occasionally its growth is surprisingly rapid, as is illustrated by the following case.

Case I.—The patient was a woman forty-four years of age who came to the clinic in January, 1927 complaining of "goiter" (Fig. 181). She stated that

Struma lymphomatosa, as described by Hashimoto, is a diffuse lymphoid infiltration of the thyroid resulting in a symmetrically enlarged, firm, hard thyroid. Here, too, the normal contour of the thyroid is not lost, and there is no fixation of the gland to adjacent cervical structures, although there is close attachment to the trachea. The disease usually occurs in women in middle life or later. There are no signs of local inflammation. The correct diagnosis is ordinarily not made clinically, although chronic thyroiditis may be suspected.

When sudden hemorrhage into an adenoma has taken place, the history reveals important points in the differential diagnosis. There may or may not be a history of a previously existing goiter. Usually the patient will relate that after exertion there was a sudden increase in the size of the neck. This may take place over a period of a few hours or a day, and accompanying this there may be symptoms of choking and pressure in the neck. Local tenderness may be marked. The swelling is asymmetrical and confined to one lobe, which frequently is very firm and hard. The tumor, after a few days, begins to subside, and gradually becomes smaller as a result of the partial absorption of the hemorrhagic content of the cyst. The time factor and the decrease in the size of the tumor are most important in the differential diagnosis.

Calcified adenomata may be very confusing from the standpoint of differential diagnosis, because they present the firmness of a malignant adenoma, may have a somewhat irregular contour, and are unilateral. However, there will be no fixation. The differential diagnosis may readily be established with the aid of a roentgenogram, which will show the calcified areas. The radiologic demonstration of calcium in a thyroid tumor is strong evidence against malignancy.

After a diagnosis of malignancy of the thyroid is established, the important question is whether or not the lesion has metastasized. Dinsmore and Hicken⁸ have recently reviewed the Cleveland Clinic series of metastatic malignancies of the thyroid. The following chart shows the sites at which metastases occurred:

Clinic only one such case has been found that was associated with suspected malignancy. This patient, in addition to her definite exophthalmos and recurrent hyperthyroidism, presented many of the clinical characteristics of malignant adenoma, but the diagnosis could not be confirmed histologically. Clute and Warren⁷ report 4 cases in a series of 226 cases of malignancy of the thyroid.

In our series about 63 per cent of all the malignancies occurred in women. Malignancy usually appears in the fifth and sixth decades of life; however, its occurrence is frequent enough in individuals under thirty-nine years of age that the clinician should keep the possibility of malignancy in mind when examining nodular goiters in young patients. Cases have been reported to occur in the first and second decades of life, and a relatively high percentage in the third and fourth.

It is necessary for the clinician to differentiate thyroid malignancy from acute thyroiditis, chronic thyroiditis as described by Riedel and that described by Hashimoto, from sudden hemorrhage in a benign adenoma, and from calcified adenoma.

A respiratory tract infection usually precedes acute thyroiditis by a few days or weeks. The patient has a symmetrical enlargement of one or both lobes of the thyroid gland and there is no distortion of the contour of the lobe or lobes. Local tenderness is very marked, and there may be a low-grade fever. Not infrequently, symptoms and signs are present which suggest a mild degree of hyperthyroidism.

Riedel's struma usually occurs in patients under 40 years of age who, in many instances, have adenomatous goiters. The outline of the thyroid lobes is destroyed. The disease frequently involves only a localized area or one lobe of the gland. The thyroid becomes adherent to surrounding structures with extensive involvement of adjacent cervical tissues. Local tenderness is frequently noted and pressure symptoms are usually marked. At times it may remain for the pathologist to make the correct diagnosis.

right lower pole of the thyroid about the size of a small hen's egg. This was removed and found to be a tumor of exactly the same type as that removed at the primary operation. The patient was observed from time to time, but returned again three months later (September, 1923) with another recurrence. At this time, a mass occupied a position higher up in the neck adjacent to and including the sternocleidomastoid muscle. This mass was removed, together with a large portion of the muscle. The diagnosis at this time was again malignant adenoma.

In April, 1925 the patient returned with a mass the size of a large marble on the left side which was just posterior to the sternocleidomastoid muscle, extending deeply into the neck and firmly attached to the surrounding tissues. This mass was carefully dissected from the carotid sheath.

In September, 1928 a small nodule was removed from the level of the left sternoclavicular joint. The same type of neoplastic tissue was again found within the capsule.

In October, 1928 two small nodules were removed from the skin above the scar on the left side.

In April, 1930 a small recurrent nodule occurred on the right side of the neck anteriorly, near the midline. This tissue was also removed and the same pathological picture was noted.

The patient returned in September, 1931 with extensive recurrence which involved the clavicle and first rib on the left side and compressed the trachea. No treatment was given at this time.

In May, 1932 there was little change in the mass on the left side of the neck. The general condition seemed excellent and the patient stated that he felt and worked better than he had for years.

In October, 1932 he returned with only a small chink between the vocal cords. The larynx was so twisted that the cords were almost horizontal and breathing was labored.

Examination in August, 1933 showed the trachea and larynx to be smooth, and free of involvement. There was a recurrent mass on the left side of the neck.

In October, 1934 the mass on the clavicle seemed to be no larger; it pulsed, and radiographs showed some osteogenesis and definite limitation of the growth. There was some induration and infiltration of the scar on the left side of the neck. x-Ray therapy was given to the clavicle.

The patient was again seen in April, 1935. He had had several small hemorrhages from the trachea. The growth on the left side seemed to be enlarging to the right and pushing the trachea further to the left. The metastatic tumor in the clavicle was smaller. He was admitted to the hospital in May, 1935 because the bleeding from the trachea had been more profuse. Bronchopneumonia developed and the patient expired about ten days after admission.

Necropsy showed that there had been direct extension of the tumor to the trachea, the left clavicle, sternum, right clavicle, and the first ribs, the left being involved more than the right. There were metastatic lesions in the lungs and liver.

This case illustrates that surgery and irradiation can accomplish a great

SITUATION OF METASTASES IN THYROID MALIGNANCY

Lungs	36
Bones	18
Cervical nodes . .	94
Axillary nodes . .	3
Brain	5
Liver	2
Soft tissues	2
Intra-abdominal . .	1

The kidneys, heart and eyes are reported as uncommon sites for metastatic lesions.

Involvement of the cervical nodes can usually be determined clinically. Such involvement, in itself, is not a contraindication to surgical treatment because these lesions can be excised at the same time the primary operation is performed.

Symptoms of cough, dyspnea and hemoptysis in the presence of malignancy of the thyroid should make one suspicious of pulmonary metastasis. There may be no physical findings indicative of such a complication, but roentgen examination of the chest will establish the presence or absence of metastases in the lungs. All degrees of involvement may be present. These may vary from a solitary metastatic nodule to multiple small embolic lesions of the lung which give a roentgenographic impression of an exudative process.

Attention may be called to skeletal metastases by pain or a tumor mass. Here again, roentgen examination establishes the definite diagnosis.

Metastatic or recurrent lesions do not contraindicate x-ray treatment. While a cure may not be effected, the comfort of the patient may be improved considerably and, in some instances, the span of life considerably lengthened, as is illustrated by the following case.

Case II.—The patient was a man, forty-six years of age, who had a large tumor on the right side of the neck which had extended to the left of the third rib on the right side. In January, 1916 the tumor was removed, some difficulty being encountered in dissecting it from the thorax. The space left by the tumor became entirely obliterated by the pleura, and the marked engorgement of the veins of the neck disappeared. The pathological report at the time of this operation was malignant adenoma.

Seven years later (June, 1923) the patient returned with a tumor in the

THE DISEASES OF THE THYROID GLAND AND THEIR RESPONSE TO ROENTGEN AND RADIUM THERAPY

U. V. PORTMANN

IN order to determine what results may be expected from roentgen and radium therapy for the treatment of different diseases of the thyroid gland, it may be desirable to review briefly some of the effects of radiation upon tissues and apply this information to the pathological conditions in which the thyroid is affected.

THE EFFECTS OF IRRADIATION UPON TISSUES

The effects of roentgen or radium rays upon tissues is brought about primarily by injury to cells. Normal or pathologic cells, and therefore tissues, vary considerably in their sensitivity or resistance to this damage. One of the oldest basic laws concerning the relative degree to which tissues respond to destruction by radiation states that "immature cells and cells in an active state of division are more sensitive to radiation than are cells which have acquired their adult morphologic and physiologic character." Accordingly, embryonic cells and neoplastic cells which are undergoing cellular division and tissues which are growing may be injured by radiation, while most normal tissues which have attained their physiologic destiny are relatively resistant.

But even neoplastic tissues vary in their radiosensitivity according to their rate of growth and their degree of differentiation or the nearness of their approach to the morphologic and physiologic character of the normal cells from which they originated. Normal tissues may also be radiosensitive or resistant, according to their degree of differentiation from their primordial cells, their reproductive capacity and the specialization of their physiologic function. For example, the leuko-

deal for here was a patient who for nineteen years lived a useful, productive life, even though recurrent and metastatic lesions developed after the original diagnosis was made.

When irradiation is administered it should be given not only at the site of the primary lesion, but also over the areas of the metastases.

Portmann⁹ reviewed the results obtained in 222 cases of thyroid malignancy seen at the Cleveland Clinic. In 36 instances where operation was deemed inadvisable, the average length of life of the patients living at the end of the period of observation was forty-one months and of those dead, twenty-seven months. Of 78 cases of proved malignant adenoma, 32 per cent of the patients were alive for an average of six and one quarter years. Papillary carcinoma was present in 15 patients, 9 of whom were alive for an average of six years.

For the most part, the results of treatment in the remaining types of malignant disease of the thyroid gland have not been so favorable. However, these remaining groups compose a very small percentage of the total thyroid malignancies. Therefore, we feel that the outlook for the patient suffering with a thyroid malignancy is better than is generally supposed.

THE DISEASES OF THE THYROID GLAND AND THEIR RESPONSE TO ROENTGEN AND RADIUM THERAPY

U. V. PORTMANN

IN order to determine what results may be expected from roentgen and radium therapy for the treatment of different diseases of the thyroid gland, it may be desirable to review briefly some of the effects of radiation upon tissues and apply this information to the pathological conditions in which the thyroid is affected.

THE EFFECTS OF IRRADIATION UPON TISSUES

The effects of roentgen or radium rays upon tissues is brought about primarily by injury to cells. Normal or pathologic cells, and therefore tissues, vary considerably in their sensitivity or resistance to this damage. One of the oldest basic laws concerning the relative degree to which tissues respond to destruction by radiation states that "immature cells and cells in an active state of division are more sensitive to radiation than are cells which have acquired their adult morphologic and physiologic character." Accordingly, embryonic cells and neoplastic cells which are undergoing cellular division and tissues which are growing may be injured by radiation, while most normal tissues which have attained their physiologic destiny are relatively resistant.

But even neoplastic tissues vary in their radiosensitivity according to their rate of growth and their degree of differentiation or the nearness of their approach to the morphologic and physiologic character of the normal cells from which they originated. Normal tissues may also be radiosensitive or resistant, according to their degree of differentiation from their primordial cells, their reproductive capacity and the specialization of their physiologic function. For example, the leuko-

cytes which are reproducible and the germinal cells of gonads which are constantly renewed until they are finally exhausted and which are a biologic luxury and not a necessity, are very sensitive to the direct destructive influences of radiation, but brain cells without regenerative power and with highly specialized functions are most resistant.

Important indirect changes are also created in tissues by damage to the radiosensitive endothelial living cells of capillaries and lymphatics. When these cells are affected, they undergo degenerative changes which result in thrombosis of the vessels by cellular débris, exudation occurs and fibrosis eventually causes the tissues nourished by these vessels to become avascular and consequently their activities are curtailed.

In the case of inflammatory tissues, the effect of radiation is also primarily destructive. A good explanation of the *modus operandi* is that the radiosensitive and the phagocytic leukocytes, which mobilize about an inflammatory focus and carry antitoxins, are destroyed, so that an excess of these protective substances is liberated in the tissues and the toxins are neutralized.

As a result of the direct and indirect destructive effect upon cells and the reactions in tissues, radiation may be employed to suppress, modify or abolish physiologic activities of organs, to create reactionary changes which prevent the progressive development of inflammation at certain stages or to inhibit or destroy malignant growth. Therefore, in some constitutional disturbances in which functional derangement of the thyroid seems to play a rôle, or in the presence of inflammation of the gland or neoplastic diseases, the patient may be benefited by roentgen or radium treatment according to the fundamental character of the pathologic process that created the disease condition.

THE PATHOLOGY OF NONTOXIC AND TOXIC GOITERS

The thyroid gland undergoes physiologic and pathologic changes which are so closely associated that it may be dif-

difficult to differentiate between the normal and the abnormal on the basis of variations or similarities in the morphologic structure of the gland. The histology which is consistent with some phase of morphologic changes known to be associated with physiological processes may be found under conditions which are distinctly pathological from the standpoint of the clinical manifestations of abnormality. Therefore, much confusion has resulted from attempts to differentiate or classify different types of goiter on the basis of histology alone. The simplest classification takes into consideration aspects of thyroid disease which are evidenced by clinical signs and symptoms of constitutional toxicity or absence of toxicity in which the gland plays some indeterminable rôle. But in the presence of either nontoxic or toxic states, the morphology throughout the glands may be similar.

The morphology consistent with physiologic changes includes hypertrophy, hyperplasia or both, and involution. The pathologic changes are degenerative and include atrophy, fibrosis and inflammation. Varying degrees of any or all of these physiologic and pathologic morphologic changes may be found in a thyroid in association with constitutional manifestations of toxicity or without them, but no single change or combination of these alterations indicate any particular disease.

Those physiologic or pathologic stimuli which cause the thyroid to become enlarged by hypertrophy, hyperplasia or involutional changes produce a "diffuse goiter." The only symptoms from such a goiter may be caused by the gross mass which produces pressure upon neighboring structures or an unsightly deformity of the neck. However, under other indeterminable conditions, the structure consistent with diffuse goiter, with or without much enlargement of the thyroid, may be associated with constitutional disturbances which are recognized as toxic in their effect and which are given many names, such as Graves' disease, Basedow's disease, thyrotoxicosis, hyperthyroidism, dysthyroidism, exophthalmic goiter, or "toxic goiter."

Also in addition to diffuse nontoxic goiters another type of

morphology may be found, and this is manifested by areas which have an adenomatous structure; these areas vary in size from microscopic to clinically palpable nodules. These nodular adenomatous changes may occur without constitutional evidences of toxicity as, for example, in those goiters which have been called simple or endemic or "nontoxic" and also in association with the clinical syndrome of "toxic goiter," which is designated by such names as exophthalmic goiter or toxic adenoma, etc., and which are "nodular goiters." These occur most frequently in adults and may represent an advanced or adult involutinal stage following a diffuse type of goiter, and hyperplasia may be present or even predominate in many cases.

Dr. Allen Graham summarizes the matter as follows: "We have found no anatomical, histological, chemical or pathological qualities in adenomata or adenomatous thyroid tissue, such as would furnish a reliable basis for distinction between toxic and nontoxic goiter. We have found colloid adenomata in hyperplastic thyroids, and hyperplastic adenomata in colloid thyroids and this may occur in either toxic or nontoxic goiter."

Since the histology of the thyroid alone cannot be a basis for distinguishing the different types of goiter, the American Society for the Study of Goiter has suggested the division of these functional changes into the nontoxic and toxic goiters and recognizes that either of these two clinical types may be diffuse or nodular goiters from the standpoint of morphology.

THE EFFECTS OF IRRADIATION UPON NONTOXIC GOITER

The cells of the thyroid gland are not embryonic, are not in an active state of division, although they may be undergoing involutinal changes, and the organ has highly specialized functions. We therefore would not expect normal thyroid cells to be radiosensitive, and this has been proved by clinical and experimental observations. Since either nontoxic or toxic goiters are composed of tissues occurring in normal thyroids and are pathologic because of the influence of extraneous

physiologic processes which create involutional (or degenerative) changes of quantity rather than quality of tissue, or else because the goiter is associated with constitutional disturbances in which the morphology of the gland may be similar to that found under normal conditions, we would not expect therapeutic radiation to change the structure of the organ from one involutional state to another nor to reduce the size of a goiter by direct destruction of thyroid cells. Therefore, irradiation is not indicated for the nontoxic diffuse or nodular goiters because they only represent involutional changes in the gland and except for their bulk, they produce no subjective difficulty. When the size of a nontoxic diffuse or adenomatous goiter is disturbing, it may be treated successfully by medical or surgical measures.

However, we know that irradiation may alter the function of an organ by affecting its vascular supply or by a direct inhibition of cellular physiologic processes and this is especially true of all secretory glands. In the constitutional disturbances associated with either diffuse or nodular toxic goiters, suppression of the activity of the thyroid by irradiation may relieve the symptoms in some cases even though the morphology of the tissue is not materially altered with the possible exception of the production of some degree of fibrosis. The same clinical result is also obtained by removal of a part of the thyroid gland.

THE TREATMENT OF TOXIC GOITER

It is not my purpose to discuss the relative merits of surgical operations or irradiation in the treatment of toxic goiter. Usually arguments about the subject are based upon prejudices and simply amount to presentations of the objections to each procedure rather than the benefits. There are numerous reports in the literature which may be reviewed for making comparisons. Radiologists report from 75 to 80 per cent of their patients cured or improved, about 15 per cent have recurrences or are unimproved and a mortality of from 5 to 12 per cent, if all patients are included who died of the disease

after irradiation. It would appear that these results compare quite favorably with the statistics of the surgeons.

Roentgen Therapy.—In the treatment of toxic goiter with roentgen rays, the tendency is toward moderate rather than intensive irradiation, the important control factor being the condition of the patient. The indications for the frequency or intensity of individual treatments or series of treatments should depend upon a decrease or increase of symptoms as manifested by changes in the basal metabolic rate, in the pulse rate, loss or gain of weight, and improvement in the subjective symptoms.

The technical and mechanical factors which are employed depend to some degree upon the personal preference or experience of the radiologist. These details are rather unimportant. Moderately penetrating rays are generally preferred, a peak voltage of from 90 to 140 kv. being employed with filtration by from 4 to 8 mm. of aluminum or its equivalent to produce an effective wavelength of from 0.28 to 0.29 angstrom. The milliamperage, time and focal distance from the skin are factors of choice by the individual operator and depend to a great degree upon the intensity of the output by the apparatus employed, of which no two are exactly alike. Most radiologists seem to prefer to administer to each field from 150 to 250 roentgen at each treatment, the dosage being calculated to include back-scattering from the skin.

In order to avoid any great amount of scattered radiation which might damage the larynx and trachea, these organs must be carefully protected. It is customary to irradiate the right and left lobes of the thyroid separately, although this is unnecessary *from the standpoint of actual dose absorbed into the gland.*

Some radiologists also administer the dosage over the mediastinum in order to irradiate the thymic area. The inclusion of this region, although considered important by some radiologists, would seem to be unnecessary in many instances, unless previous radiographs of the chest show the existence of a substernal goiter which might be active or show some evi-

dences of the presence of abnormal lymphatic tissue within the mediastinum. Although thymic tissue may be found in the mediastinum, especially in young individuals, it probably does not contribute to the toxic state, but it is a part of the generalized lymphatic reaction which is always associated with toxic goiter, and therefore the necessity for the routine treatment of the mediastinum is debatable.

The frequency of roentgen treatments depends upon the severity of the symptoms and the reaction in the individual case. In the beginning of a series of treatments, once a week is usually considered to be often enough, or the treatments may be spaced at longer intervals, the average being about two weeks. Usually from 6 to 8 treatments constitute a series. A careful record of the pulse rate, weight and subjective symptoms should be kept, and the basal metabolic rate should be determined before each treatment, the course and dose being governed accordingly. The number of series which may be given will vary with the indications in the individual case, but it would seem advisable to discontinue treatment if decided improvement is not manifested within two or three months.

Radium Therapy.—The intensity of radiation with radium, which is administered for toxic goiter, will naturally depend upon the quantity of radium which is available. Usually radium packs are used and about one third of an "erythema dose" is administered to each lobe at each treatment, the trachea being protected. For example, with a 4×4 cm. pack at 2 cm. distance and a filter equivalent to 4 mm. of brass, the dose would be 400 mg. hours.

The frequency and intensity of radium treatments should be governed in the same way as in the roentgen-ray treatment.

A few radiologists have employed interstitial radiation by means of radon gold seeds or needles. I believe interstitial radiation is inadvisable because of the necessity for the surgical procedure involved, which is attended by as much hazard as thyroidectomy. Moreover, the radiation effects cannot be controlled accurately because no one can predetermine the exact intensity of radiation which will be necessary to con-

trol the symptoms. If too much thyroid tissue is destroyed, hypothyroidism may result, and if too little is applied, the patient will not be relieved or the treatment must be repeated.

THE TREATMENT OF INFLAMMATIONS OF THE THYROID

Acute Simple Thyroiditis.—Acute inflammation of the thyroid gland is manifested by the usual symptoms of inflammation, namely, rather rapid swelling, local heat, tenderness, pain and fever. The process may progress to abscess formation. The treatment consists in the local application of cold and of small doses of roentgen rays, which will have an analgesic effect about the inflammation and shorten convalescence. If the inflammatory process has progressed to an abscess stage, the roentgen treatment will hasten the breaking down and drainage incisions may be made very promptly. Therefore, roentgen treatment may be instituted with benefit at any stage of the inflammation, although it is more beneficial when applied early and it is hazardous to administer dosage of great intensity at one treatment.

Chronic thyroiditis, Riedel's struma or ligneous thyroiditis is a chronic inflammation of the thyroid gland which is manifested by a quiet painless swelling of fairly rapid growth. The gland is very hard and fixed, and in about one half the cases the condition is bilateral. The obstructive symptoms are prominent very early in the course of the disease. Because of the similarity of the signs and symptoms, it is very difficult and sometimes impossible to differentiate this condition from malignant disease except possibly by the rate of growth. When a clinical diagnosis can be made, roentgen therapy is the preferred treatment. The intensity of radiation which should be applied is somewhat greater than that employed for acute inflammation; however, immediately after the treatment, swelling of the gland may occur which may be relieved by hot applications. When there is marked obstruction a tracheotomy may be necessary.

Tuberculosis of the Thyroid Gland.—This produces a more or less chronic inflammation of the thyroid, which is sel-

dom recognized clinically, and is often difficult to diagnose, even by means of microscopic sections. The pathologic process and its manifestations are the usual manifestations of tuberculosis. Tuberculous inflammation of the thyroid may invade adjacent lymphatics and other tissues, and rarely may form a tuberculous abscess. When tuberculosis of the thyroid is recognized, it should be treated by small doses of roentgen rays to relieve lymphocytic infiltrations and create the production of fibrous tissue just as in the case of tuberculous lesions in other localities.

STRUMA LYMPHOMATOSA

This is a rare disease of the thyroid which is manifested by the presence of a large amount of lymphatic tissue in the thyroid gland and is associated with some fibrosis and atrophy. Clinically, there is a diffuse, bilateral, quiet and rapid enlargement of the thyroid gland which, in contrast to Riedel's struma or a neoplasm, is not adherent to adjacent structures. There are a few symptoms and no evidence of toxicity but late in the disease some obstructive symptoms may develop because of fibrosis. One patient whom I treated was diagnosed clinically as having an inoperable neoplasm of the thyroid, but one year later, in spite of radiation, the goiter had not decreased in size and the obstructive symptoms were increased. Subsequently an operation was performed and the true condition was recognized. It is probable that radiation treatment of this condition increases the fibrosis and from clinical evidences at least, it is of no benefit.

It is recognized that struma lymphomatosa may develop into lymphosarcoma; when this occurs, intensive radiation is indicated. In such cases radiation may result in relief or cure.

MALIGNANT GOITER

Within recent years better understanding of malignant disease has brought the realization that the histologic morphology of tissue is not always a criterion by which neoplasms can be differentiated or classified, and does not always indicate what

trol the symptoms. If too much thyroid tissue is destroyed, hypothyroidism may result, and if too little is applied, the patient will not be relieved or the treatment must be repeated.

THE TREATMENT OF INFLAMMATIONS OF THE THYROID

Acute Simple Thyroiditis.—Acute inflammation of the thyroid gland is manifested by the usual symptoms of inflammation, namely, rather rapid swelling, local heat, tenderness, pain and fever. The process may progress to abscess formation. The treatment consists in the local application of cold and of small doses of roentgen rays, which will have an analgesic effect about the inflammation and shorten convalescence. If the inflammatory process has progressed to an abscess stage, the roentgen treatment will hasten the breaking down and drainage incisions may be made very promptly. Therefore, roentgen treatment may be instituted with benefit at any stage of the inflammation, although it is more beneficial when applied early and it is hazardous to administer dosage of great intensity at one treatment.

Chronic thyroiditis, Riedel's struma or ligneous thyroiditis is a chronic inflammation of the thyroid gland which is manifested by a quiet painless swelling of fairly rapid growth. The gland is very hard and fixed, and in about one half the cases the condition is bilateral. The obstructive symptoms are prominent very early in the course of the disease. Because of the similarity of the signs and symptoms, it is very difficult and sometimes impossible to differentiate this condition from malignant disease except possibly by the rate of growth. When a clinical diagnosis can be made, roentgen therapy is the preferred treatment. The intensity of radiation which should be applied is somewhat greater than that employed for acute inflammation; however, immediately after the treatment, swelling of the gland may occur which may be relieved by hot applications. When there is marked obstruction a tracheotomy may be necessary.

Tuberculosis of the Thyroid Gland.—This produces a more or less chronic inflammation of the thyroid, which is sel-

omas of the thyroid which originate in preexisting adenomas, exclusive of the papillary cyst adenomas. He has found that this group constitutes about 90 per cent of all malignant lesions of the gland, and at least 90 per cent of the epithelial thyroid malignancies can be proved to have originated in pre-existing adenomas.

When a preexisting benign adenoma of the thyroid undergoes malignant degenerative changes the growth may present many combinations of morphologic transitions such as fetal, intermediate or mixed colloid adenomas, and any one, two or all of these transitions may be found in a single tumor; in fact, it is seldom that only one type is found. Therefore, adenocarcinoma, medullary carcinoma, scirrhus carcinoma, papillary carcinoma or carcinoma resembling sarcoma or any combination of these forms may develop as a malignant adenoma, or may be found in thrombi within the vessels. Because of this variability of structure, it is difficult to make a diagnosis of the type of growth on the basis of morphology; therefore, before the true character of the neoplasm can be established, it is necessary to study the type of structure of the preexisting adenoma, its duration and rate of growth, the character and reaction of the stroma, and especially the evidence of invasion of the blood vessels.

Malignant adenomas are primarily encapsulated by the connective tissue which surrounds the preexisting adenoma, but since the neoplastic epithelial cells lie in direct contact with numerous blood vessels in and around the tumor, these will be filled with neoplastic cells in almost every instance by the gradual expansion and invasion of the growth. Neoplastic cells may escape into the vessels of the adenoma and metastases may occur by way of the blood stream even though the growth may not have broken through its own capsule. This manifestation in the blood vessels is characteristic and distinguishes malignant adenomas regardless of the histologic structure.

Malignant adenomas are found in patients past middle age in whom goiters, which have been present for a long time, have begun to enlarge rapidly. The progress of the enlarge-

may be their clinical course. This is particularly true of the malignant tumors of the thyroid gland, there being certain points in their origin, development, structure and growth characteristics which are just as important as their microscopic morphology and must be taken into consideration in order to distinguish the different types of growth and to understand the reasons for their peculiar variations. Therapeutic procedures should be planned on the basis of the growth characteristics of each different type of neoplasm.

Certain characteristics of the thyroid gland give indications as to the types of malignant goiter which may occur.

1. Thyroid tissue consists largely of glandular epithelial cells. Hence on the basis of the laws of probability, epithelial neoplasms or carcinomas should occur with proportionately greater frequency than the mesothelial neoplasms or sarcomas.

2. The character of the concentric and hyperplastic development of the thyroid glandular structure predisposes to the production of localized adenomatous tumors which may undergo many kinds of degenerative changes, including malignancy, because of their inherent embryonic stimulus to hyperplastic growth; therefore malignant growths which originate in such adenomatous tumors should occur with relative frequency.

3. The acini of the thyroid have no basement membrane, and because their cells lie in such close proximity to the vessels, they may readily penetrate into the circulating blood and may quickly be distributed to different parts of the body as metastases.

4. The lymphatic distribution and drainage of the thyroid cause the fairly early involvement of the deeper cervical lymph nodes by certain types of malignant processes, and frequently this occurs before the involvement can be determined clinically, and the abundant intracapsular plexus permits direct extension to adjacent structures, particularly to the trachea.

Malignant Adenomas.—The term malignant adenoma was suggested by Dr. Allen Graham to designate those carcin-

are sometimes palpably enlarged. They grow very slowly but progressively, and are of low-grade malignancy from the standpoint of rapidity of growth, but they destroy life by local constriction even before metastases develop.

Papillary Carcinoma.—Adenomas of the thyroid, like adenomas in other organs, may also undergo cystic degeneration and in turn these cystic adenomas may become malignant. When this occurs, multiple finger-like processes are formed in the walls of the acini in the arrangement which is characteristic of papillary carcinoma. The growth is at first confined within its capsule, but gradually the neoplastic columnar cells of the papillae invade and break through the thin stroma at the base of the acini in which they develop, and thus extend to adjacent acini and the lymphatics. They do not invade blood vessels because the cysts in which they originate are avascular, and because they are primarily encapsulated and confined. As would be expected from the nature of their origin and the character of their growth, these neoplasms are of a comparatively low grade of malignancy. As indicated previously, some malignant adenomas may contain areas with papilliferous formation.

Clinically, the papillary carcinomas are usually unilateral, rather firm, nodular tumors, which grow slowly, but sometimes become very large. As the tumor progresses, the structures about it are infiltrated and compressed, and the skin may become red and edematous with eventual breakdown and ulceration.

Carcinoma-sarcoma.—A rare tumor of mixed carcinoma and sarcoma occurs in the thyroid. The epithelial structures show changes characteristic of carcinoma and the abundant stroma presents the appearance of fibrosarcoma. There are numerous mitotic cells arranged atypically in both epithelial and mesothelial elements. Theoretically, this type of tumor may begin as carcinoma which, because of some peculiarity of growth or physiologic reaction, causes neoplastic stimulus to the stroma so that it also becomes malignant. However, there is little proof of the theory. Usually, this

ment may be relatively slow, even with occasional regressions unrelated to any physiologic process. A hard tumor is found in the thyroid, usually unilaterally, but a smooth, firm, general enlargement occasionally occurs, depending somewhat upon the duration and the rate of growth.

A clinical diagnosis can be made in about one half the cases, the others being discovered by the pathologist after removal of thyroid tissue from goiters, supposedly benign.

Adenocarcinoma Not in Adenoma.—Occasionally, a peculiar lesion is encountered in the thyroid which may be called "adenocarcinoma not originating in adenoma." This lesion has some characteristics of carcinoma, but is of very low-grade malignancy. It originates in acinar epithelium, remains quite localized, is not encapsulated and no mitotic figures are demonstrable. It might be called "carcinomatoid," and is only of interest to pathologists, because it gives no clinical signs or symptoms, is not fatal and is of no importance to the radiologist.

Scirrhus Carcinoma.—The kind of stimulus to neoplastic growth which causes a scirrhus carcinoma to develop in the thyroid gland produces the same histologic changes in this organ as are found in scirrhus carcinomas in other structures. Fibrous tissue predominates and the neoplastic epithelial cells occur in masses of strands as though the malignant reaction were held in restraint so that glandular arrangement cannot take place. The growths are not encapsulated and, therefore, progressively invade the surrounding tissues which they destroy by infiltration through the lymphatics and compress the blood vessels in fibrous tissue. It cannot be determined that scirrhus carcinomas of the thyroid begin in adenomas, although there is no reason why they should not do so. As previously mentioned, a malignant adenoma may present localized areas of scirrhus formation along with other types of malignant changes.

These neoplasms seldom are discovered early by clinical examination but in the late stages and after recurrence, they are extremely hard and fixed, and the invaded lymph nodes

particularly in the bases and they gradually enlarge and coalesce as the disease progresses or large solitary tumors may be seen.

Metastases may also occur in bones, especially in the long bones, but also to some extent throughout the rest of the skeletal system. When roentgen examination reveals an otherwise unexplainable, but obviously malignant lesion in a bone, the thyroid should be suspected as the primary source of a neoplasm, even though there may be no other evidence of disease of this organ.

Occasionally, metastases occur in soft tissues as slowly growing tumors without any definite clinical characteristics, and only microscopic examination will disclose their thyroid origin.

Distant metastases are almost always from malignant adenomas. They develop from neoplastic cells which have invaded blood vessels, become detached and are distributed through the circulation and form neoplastic emboli in various locations. Because these metastases have the histologic morphology and probable function of the parent neoplasm which may closely resemble normal thyroid tissues, they have been mistaken for aberrant thyroid rests.

When metastases are present, operations upon the thyroid usually are not indicated. However, even when metastases are present or when the growth has invaded the structure contiguous to the thyroid, it may be necessary to perform a decompression operation to remove some of the growth, or to perform a tracheotomy in order to relieve respiratory difficulty. Roentgen irradiation should be administered following such palliative operations to inoperable neoplasms and to metastases, some of which may thus be held in check for some time.

TREATMENT OF MALIGNANT GOITER AND ITS RESULTS

The procedure for the treatment of a malignant tumor of the thyroid should be based upon its known growth characteristics. In only about 50 per cent of cases can a clinical di-

tumor is erroneously considered to be carcinoma, or is occasionally classified as fibrosarcoma, depending upon the type of cells which are found. There is no possibility of differentiating this growth clinically; it must be distinguished by microscopic examination. It appears as a hard, rapidly extending mass in a lobe of the thyroid.

Sarcoma.—True sarcomas of the thyroid are rare in spite of the fact that the literature contains many reports of such cases. If the relative proportion of mesothelial elements to the epithelial structures is taken into consideration, it must be realized that sarcomas should be comparatively uncommon. The usual mistake is to call a very cellular, malignant adenoma a sarcoma. However, sarcomas originate in the mesoblastic elements of the stroma, and a study of different regions will usually distinguish them from malignant adenomas by the absence of epithelial cells in the tumor.

The most common type of sarcoma of the thyroid is lymphosarcoma and it has the same characteristics as similar neoplasms in any other organ. The growth is highly malignant and quickly infiltrates the thyroid and adjacent structures. Clinically, patients with lymphosarcoma give a short history of very rapid growth, and usually the entire organ is firm and fixed and the patient complains bitterly of choking. The rapid infiltration of the gland and adjacent structures, particularly extension into the upper mediastinum, usually destroys the host before distant metastases become evident.

Fibrosarcomas, or spindle cell sarcomas, originating in the stroma also are seen occasionally, but they are very rare. They grow more slowly than lymphosarcomas, and clinically are indistinguishable from other tumors.

Metastases.—Every patient for whom an operation on the thyroid is contemplated should first have a roentgenographic examination of the chest. Such an examination may reveal unsuspected, benign, intrathoracic or substernal thyroids or metastases from a malignant goiter that may or may not be discovered by clinical examination. Pulmonary metastases usually are seen as a shower of small nodules of various sizes,

very hard growth. It is almost a certainty that such a growth has invaded the lymphatics and other structures contiguous to the thyroid and has extended widely through the lymphatics, and for this reason cannot be entirely excised. Scirrhus carcinomas are highly resistant to irradiation, and since they destroy life before distant metastases develop, interstitial irradiation followed by roentgen irradiation should be administered, although even with this procedure, the prognosis is very bad.

Occasionally, a papillary carcinoma may be so localized and encapsulated that it may be excised completely, but when there is clinical, gross or microscopic evidence or a suspicion that the growth has extended through the lymphatics into the surrounding thyroid gland structure or adjacent tissues outside the field of operation, irradiation should be administered. These growths do not invade blood vessels early as do malignant adenomas, and therefore the application of interstitial irradiation is not so hazardous. If and when this type of growth is recognized at operation, interstitial irradiation may be applied at once, to be followed later by roentgen treatment. If the neoplasm is discovered subsequent to operation, it is advisable to depend upon roentgen irradiation unless the growth continues, and then a second more extensive operation and implantation of radium in one form or another may be necessary. Some of these growths yield to irradiation.

TECHNIC OF IRRADIATION

The technic of applying radium to malignant goiters should be planned according to the type and size of growth. The more resistant neoplasms should be given as great an intensity as is possible. Gold radon seeds may be employed but the trachea and large vessels should be avoided in making the implantations. As has been pointed out, it is better not to thrust needles into malignant adenomatous tissue, and so roentgen irradiation should be employed primarily, and this should be followed by interstitial irradiation if necessary.

In administering roentgen irradiation we have been using

agnosis be made before operation; therefore, half of these patients have had some sort of operation and the true nature of the tumor is only discovered by the pathologist.

When a definite diagnosis of malignant goiter can be made by clinical examination, the condition usually is inoperable from the standpoint of curability because of the probability of invasion of the vessels in the tissues which cannot be removed. Sometimes, however, palliative operations are advisable and at least a biopsy should be done to determine the type of neoplasm in order that a logical therapeutic régime may be instituted. In any case, in operating upon a patient with malignancy of the thyroid, the surgeon should always have in mind the possibility of causing embolic metastases by harsh manipulation.

When a malignant adenoma is discovered, treatment is begun with roentgen irradiation regardless of whether or not the surgeon believes he has removed all the growth, because there is always the possibility of invasion of the blood vessels outside the field of operation. Since about 90 per cent of the malignant neoplasms of the thyroid are malignant adenomas, the blood vessels are probably invaded and so interstitial irradiation is seldom employed at the time of operation. This treatment may be used with less hazard after the neoplasm has been rendered dormant by roentgen irradiation, or later, if it is obvious that the roentgen treatment has not been entirely efficacious. Most of the malignant adenomas are quite sensitive to irradiation, not only because the neoplastic cells in the tumor and those in the vessels are radiosensitive, but also no doubt, because of the secondary fibrosing and obliterating effect upon the capillaries, which prohibits further extension. Roentgen irradiation alone, especially for inoperable tumors, has been quite efficacious in our experience.

The adenocarcinomas not originating in adenomas are so localized and of such low-grade malignancy that none of them require irradiation. Of 17 patients with this carcinomatoid growth, 16 of whom have been traced, all are well.

Scirrhus carcinoma may be recognized at operation as a

PREOPERATIVE AND POSTOPERATIVE TREATMENT OF THE PATIENT WITH HYPERTHYROIDISM

GEORGE CRILE, JR.

I. GENERAL PRINCIPLES

PATIENTS with hyperthyroidism are nervous and over-reactive to stimuli. Their emotional tension is so great that it can be released by the slightest provocation into an outburst which may go on to a thyroid crisis. There is probably no other condition in which changes induced by trivial procedures can develop so rapidly into critical states that threaten life. For these reasons, the patient with hyperthyroidism must be managed with extraordinary care. The complications of hyperthyroidism (thyroid crisis, cardiac decompensation, etc.) which are so difficult to treat are, in the majority of cases, relatively easy to avoid. We must, therefore, anticipate the complications that are likely to arise and treat them prophylactically before they develop.

II. ROUTINE PREOPERATIVE CARE

1. **Physical and Mental Rest.**—The patient should be hospitalized so that she will become thoroughly accustomed to the hospital environment. She should not be allowed visitors other than members of the family; the length of the visits should be limited to fifteen minutes; there should never be more than 2 visitors present at a time; and the visitors should be asked to refrain from discussing any subject which might disturb the patient. She should not be in a room with patients who are recuperating from operations, and the nurses and doctors should not discuss the coming operation with the patient except in a reassuring way. The patient should never be notified when the operation is to be performed. When the

200 kv. and heavy filtration, giving an effective wavelength of about 0.15 angstrom or shorter.

The skin-tolerance dose is considered to be 800 roentgens when back-scattering is included, if the dose is given in one sitting. However, in the past few years we have administered four or five times this amount to each field by daily applications of from 200 to 300 roentgens and have secured much better results.

The fields are planned to crossfire anteriorly and posteriorly the thyroid area, the supraclavicular region and the upper mediastinum regardless of whether or not the growth is considered to be bilateral or to have extended substernally. The roentgen beam is directed to the midline from each portal and includes the trachea and thyroid isthmus, which should receive a therapeutic dose on account of the probability of neoplastic invasion. Inflammation within the trachea may ensue at the height of the irradiation reaction, but usually can be relieved by intratracheal injections of oil, although in some patients who have had extensive invasion necessitating large doses of radiation, a tracheotomy may be necessary. Ulceration in the trachea has been produced in a few instances, but this has not been a serious complication, and the temporary discomfort is better than death from the disease.

although occasionally improvement may be noted even after the third week. By this time, even those patients who enter on the verge of crisis are taking food and fluids well and are mentally clear. When the pulse curve has fallen nearly to the base line, when the weight curve shows a consistent rise, and when the clinical appearance of the patient indicates that she has developed as much emotional stability as can be expected, then the time for operation has arrived. Even if the basal metabolic rate is high, the patient is in as good a condition for operation as she will ever be.

III. POSTOPERATIVE TREATMENT

1. **Fluids.**—Following thyroidectomy, the patient is often reluctant to take fluids by mouth. Therefore, an infusion of 2000 cc. of normal saline solution should be given to make up for the fluid lost during the operation and to balance the losses of water through the skin, which as Coller³ has shown, are so great in patients with hyperthyroidism.

In patients with severe hyperthyroidism, it is advisable to give a 5 or 10 per cent solution of glucose in normal saline intravenously. The fluid intake, except perhaps in patients with cardiac decompensation, should be between 3000 and 4000 cc. daily. In order to preserve and replenish the glycogen reserves of the liver in patients who are not taking nourishment by mouth, it is well to give at least 150 Gm. of glucose intravenously along with the fluids. Three thousand cc. of 5 per cent glucose in normal saline given by means of the continuous intravenous drip is the minimum postoperative fluid and carbohydrate requirement of the patient with severe hyperthyroidism who is taking little or nothing by mouth. In the average case, however, fluids are taken well after the first day, and a hypodermoclysis immediately following operation will suffice.

2. **Transfusion.**—A blood transfusion given immediately after operation is valuable in patients with severe hyperthyroidism or in aged or debilitated patients. The time to start the administration of parenteral fluids, and the time to

patient knows that the contemplated operation will occur the next day, a night of worry will often ensue and the pulse may be elevated 20 or 30 points in the morning. Absolute bed rest without getting up for bathroom privileges or for any other purpose should be insisted upon. In short, the preoperative hospital stay should be a phase of complete mental and physical rest.

2. **Sedation.**—Sedatives are valuable during the preoperative period, and experience has shown us that bromides are of more value than barbiturates in patients with hyperthyroidism. Occasionally, especially in older patients or in cases of extreme hyperthyroidism, barbiturates will excite the patient or may even precipitate a maniacal state. Thirty grains of sodium bromide twice daily is usually enough to dull the edge of the overactive emotional response. If the patient is delirious, additional sedation may be necessary, and morphine is usually the most effective drug to use.

3. **Diet.**—The diet should be of high caloric content in order to balance the increased demands of hypermetabolism. It is important, especially in cases in which edema is present and in which the serum proteins are low (as is often the case in severe hyperthyroidism), to give large amounts of proteins.¹ Preoperative blood transfusions are of definite value in raising the serum proteins in extreme cases where extensive edema is present.

4. **Iodine.**—Iodine, as shown by Plummer² exerts a striking effect in the control of hyperthyroidism. The administration of 1 cc. of Lugol's solution three times daily, usually in grape juice, is an effective means of administering iodine, but sodium iodide in equivalent doses is probably equally efficient. Iodine should be given preoperatively in case of hyperthyroidism associated with any type of goiter, either nodular or diffuse.

5. **Time of Operation.**—The preoperative routine is continued until the pulse curve has come down to the point where it begins to flatten out and until it does not appear that it will fall any lower. Usually, this occurs in from one to two weeks,

tion and any elevation to 102° F. or above should be reported at once to the physician. In hot weather, it is doubly important to follow the temperature closely and it is often advisable to take hourly readings because the temperature may rise with great rapidity. The importance of the temperature factor is shown by the increased incidence of fatal thyroid crises in the hot summer months, this complication in our series being 2.4 times as frequent in these months as in the remainder of the year.

In order to prevent the rise of temperature and the vicious circle of hyperthermia and hypermetabolism that characterizes a thyroid crisis, we must refrigerate the patient to the extent that we abstract more heat than can be produced. If we fail to do this, the temperature may continue to rise to 106° F. and higher, and the patient literally burns herself up in a crisis of hypermetabolism and hyperthermia.

If 10 grains of aspirin fail to reduce the temperature, refrigeration by means of ice-bags should be started. When the temperature reaches 102° F., 6 ice-bags should be applied around the lower extremities. At 103° F., ice-bags should be placed along the sides and should completely surround the lower extremities. At 104° F., a sheet is saturated in alcohol, placed over the patient, and an electric fan is allowed to play on the sheet. If this fails to control the further rise of the temperature, the patient is literally covered with cracked ice which is held in a special rubber bag large enough to cover the entire body. Care should always be taken that the skin is protected by a flannel sheet from direct contact with the cold rubber of the bag. The ice-cooled oxygen tent, as we have mentioned before, is also of value in the control of hyperthermia.

IV. MANAGEMENT OF THE PATIENT BETWEEN STAGES OF A DIVIDED OPERATION

In the management of patients who are sent home for three months between the stages of a divided operation, either following ligations or between lobectomies, it is important to

give a blood transfusion is not after the patient's pulse and temperature are rising into a thyroid crisis, but directly after the operation, so that the postoperative reaction will be minimized. A few hours of delay may mean the induction of a vicious circle of hyperthermia and hypermetabolism. It should be remembered that the metabolic rate rises 7.2 points with each degree of rise of temperature, and that the hypermetabolism in turn results in a greater production of heat and in a further rise of temperature. The hypermetabolism, moreover, puts an additional burden on the already overstrained myocardium, auricular fibrillation not infrequently follows, and a postoperative reaction that could have been avoided by prompt prophylactic treatment may go on to thyroid crisis, cardiac decompensation and death.

3. **Sedatives.**—It is extremely important to give sedatives, preferably morphine, in doses sufficient to keep the patient comfortable, free from worry, and at rest. The administration of sedatives should not be left to the nurse, but should be under the direct supervision of a physician. The nurse will often hesitate to give morphine frequently enough to control restlessness; the patient will become anxious and excited; a further elevation of the temperature will result; and an additional burden will be imposed on the myocardium. For this reason, postoperative narcotics cannot be given at routine intervals, but should be given in accordance with the patient's needs.

4. **The Oxygen Tent.**—The oxygen tent is of great value in the treatment of postoperative thyroid reactions. The temperature often falls several degrees after an hour or two of its use. Whether this effect is the result of the oxygen, of the refrigerated air of the tent, or of a combination of the two factors, is not yet certain, but it is well established that the tent is of definite value. In bad risk cases, it is usually advisable to place the patient in the tent immediately after operation in order to forestall the expected reaction.

5. **Control of Hyperthermia.**—The temperature should be taken every two hours for the first two days after opera-

tion and any elevation to 102° F. or above should be reported at once to the physician. In hot weather, it is doubly important to follow the temperature closely and it is often advisable to take hourly readings because the temperature may rise with great rapidity. The importance of the temperature factor is shown by the increased incidence of fatal thyroid crises in the hot summer months, this complication in our series being 2.4 times as frequent in these months as in the remainder of the year.

In order to prevent the rise of temperature and the vicious circle of hyperthermia and hypermetabolism that characterizes a thyroid crisis, we must refrigerate the patient to the extent that we abstract more heat than can be produced. If we fail to do this, the temperature may continue to rise to 106° F. and higher, and the patient literally burns herself up in a crisis of hypermetabolism and hyperthermia.

If 10 grains of aspirin fail to reduce the temperature, refrigeration by means of ice-bags should be started. When the temperature reaches 102° F., 6 ice-bags should be applied around the lower extremities. At 103° F., ice-bags should be placed along the sides and should completely surround the lower extremities. At 104° F., a sheet is saturated in alcohol, placed over the patient, and an electric fan is allowed to play on the sheet. If this fails to control the further rise of the temperature, the patient is literally covered with cracked ice which is held in a special rubber bag large enough to cover the entire body. Care should always be taken that the skin is protected by a flannel sheet from direct contact with the cold rubber of the bag. The ice-cooled oxygen tent, as we have mentioned before, is also of value in the control of hyperthermia.

IV. MANAGEMENT OF THE PATIENT BETWEEN STAGES OF A DIVIDED OPERATION

In the management of patients who are sent home for three months between the stages of a divided operation, either following ligations or between lobectomies, it is important to

bear in mind the possibility that if iodine medication has been administered for a long time before the patient entered the hospital, the hyperthyroidism may be partially under control and may actually be more severe than is apparent clinically. Therefore, if the patient is sent home following, for example, a ligation, and if iodine is withdrawn before the full benefits of the operation have been received, it is possible that an exacerbation of the hyperthyroidism may occur incident to the withdrawal of iodine, and that this exacerbation may be more severe than the remission induced by the ligations. If this is the case, a thyroid crisis may ensue at home, or the patient may go on to cardiac decompensation. We believe, therefore, that following the first stage of a divided operation, iodine should be administered until the remission induced by the operation is well established.

Although we believe that iodine loses its maximum effectiveness after protracted use, iodine undoubtedly does exert a partial control of hyperthyroidism for an indefinite period of time. For practical purposes, it is therefore usually safer to give patients who are not under direct observation between the stages of a divided operation small doses (2 or 3 minims) of Lugol's solution daily.

V. INDICATIONS OF UNFAVORABLE PROGNOSIS

The only two absolute contraindications for the surgical treatment of hyperthyroidism are persistent delirium or persistent vomiting. There are, however, certain factors whose presence, although they do not contraindicate surgery, constitute a warning of an unfavorable prognosis.

In order to determine the relative prognostic significance of the various factors which generally are considered to constitute warnings, an analysis of the fatalities which followed operations for hyperthyroidism in the years from 1924 through 1934 has been made. If these warnings are classified according to the ratio between their incidence in the group of patients who died following operation and their incidence in an equal number of patients in each year who were picked at

random from those who survived operation, it is found that cardiac complications stand first in importance. In other words, auricular fibrillation, cardiac decompensation, myocarditis or valvular heart disease occurred seven times as frequently in the patients who died after operation as in those who survived operation. Substernal goiter was present six times as often in those who died following operation; a flat pulse curve, *i. e.*, a pulse curve which did not come down in response to the preoperative treatment was present five times as frequently; and the age was over 60 in five times as many

RELATIVE IMPORTANCE OF VARIOUS WARNINGS

Figures based on ratio of incidence of special warnings in patients who died following operation to their incidence in patients who survived operation

Fig. 182.

of the patients who died after operation as in those who survived. A pulse rate of over 100 at the time of operation was present 2.5:1 times as frequently in those dying after operation as in those who survived; the presence of complicating diseases, tuberculosis, diabetes, etc., but not including cardiac disorders, was in a ratio of 2.5:1 in the dead as compared to the living. A pulse rate of over 120 at entry was present in a 2:1 ratio; as was also loss of more than one fifth the body weight. An analysis of all other factors, such as the presence of nodular goiter, of a hyperplastic goiter, of pre-

operative irradiation, of duration of the disease for more than two years, of a history of iodine medication before entry, of a basal metabolic rate above plus 50 per cent, showed that each occurred as frequently in the patients who survived operation as in those who died following operation (Fig. 182).

We conclude, therefore, that the association with hyperthyroidism of cardiac complications, of a substernal goiter, of a poor preoperative response of the pulse curve, or of old age, indicates that the operative risk is increased. The mere severity of the hyperthyroidism as indicated by loss of weight or a high basal metabolic rate, however, does not imply an increased operative risk if the above complications are not present.

VI. THE PREVENTION OF POSTOPERATIVE COMPLICATIONS

Analysis of the cases which have terminated fatally following thyroidectomy shows that in those patients who have a flat pulse curve (*i. e.*, a pulse curve which does not come down in response to the preoperative treatment), in those who have a basal metabolic rate of more than plus 50 per cent, and in those who have a psychosis or clinical evidences of severe hyperthyroidism as judged by the patient's behavior, postoperative thyroid crisis is the commonest cause of death (Fig. 183). In substernal goiter in patients with preoperative pulmonary complications and in old age, the greatest risk is pneumonia (Fig. 184). Myocardial failure is the most frequent cause of death in patients with auricular fibrillation, cardiac decompensation or evidences of chronic myocardial damage and also in those patients in whom hyperthyroidism has been present for more than two years (Fig. 185).

1. The Prevention of Thyroid Crisis.—In the first group—*i. e.*, in those patients who have an excessively high basal metabolic rate, a flat pulse curve, or in those who have a psychosis—all therapeutic measures against thyroid crisis including blood transfusion, parenteral fluids, intravenous glucose, the oxygen tent, and morphine in doses sufficient to insure comfort and rest, should be used immediately following

Causes of Death

Fig. 183.

Fig. 184.

the operation and every effort should be made to control the temperature by means of antipyretics and refrigeration.

While we believe that small amounts of iodine should always be continued after operation, we never have felt that the postoperative use of large doses of iodine exerted any striking effect on the thyroid reaction of a patient who before operation had received the maximum amount of iodine. We

Fig. 185.

have shown in the experimental laboratory that the administration of iodine exerts no effect on the elevated metabolism of completely thyroidectomized dogs fed on large quantities of desiccated thyroid. The effect of iodine is, therefore, not on the tissues of the body or on the thyroid hormone circulating in the blood, but its action is rather a direct one on the secretory activity of the thyroid gland. For this reason, large doses of iodine cannot be expected to cause any

effect on the postoperative reaction of a fully iodized patient. The best we can do is to carry on with the routine small dose of iodine so that at least there will be no exacerbation of symptoms incident to its withdrawal.

If the surgeon believes that the patient's greatest hazard is from the severity of the hyperthyroidism and if the patient is relatively young and otherwise in good condition, a basal anesthesia of avertin is of definite value in calming the patient and minimizing the postoperative reaction. If, however, the patient is old or debilitated, the use of this drug is contraindicated as will be explained later.

2. The Prevention of Pneumonia.—The management of the aged patient, in whom pneumonia is the greatest hazard, is quite different. We have seen that sedation and avoidance of psychic disturbances are fundamental principles in the management of severe hyperthyroidism in the young adult. But in the aged, we must not depress the respiration or the internal metabolism of the body because of the danger of inducing a terminal pneumonia. Depressant drugs are tolerated well in the young but easily force the aged below the critical threshold at which resistance cannot overcome the ever-present tendency to pneumonia. Every resource at our disposal must be utilized to build up the resistance of the aged patient and stimulate the vital functions. Preoperative and postoperative blood transfusions are of especial value in the aged, and there can be no question as to their efficacy in increasing the patient's resistance and strength.

As we have shown already, the chief hazard in the aged is pneumonia, while death from thyroid crisis is relatively rare. Hence, in the aged, it is better to perform the operation under local anesthesia with a minimum of gas oxygen analgesia. Avertin or any general anesthesia with its secondary depression of respiration, the cough reflex, and of intracellular metabolism should be avoided even at the expense of an occasional mild psychic reaction.

In old age, the principle of the multiple stage operation should be followed, and a lobectomy should be performed if

there is any question in the mind of the surgeon in regard to the ability of the patient to withstand a more radical procedure. Pneumonia may follow even a relatively mild post-operative reaction, and the general condition of the patient as well as her status in regard to hyperthyroidism should be given prime consideration in the choice of both the time and type of operation.

The use of the oxygen tent has lessened the mortality rate from pneumonia. The aged patient with hyperthyroidism therefore should have oxygen therapy at least as soon as any signs of pulmonary congestion occur. In addition, we believe that the severity of the thyroid reaction has been reduced by the use of the oxygen tent, and that bad-risk patients of all ages make better progress when oxygen therapy is started immediately after the operation.

In the aged, ice packs should be applied only when absolutely necessary, so that chilling with its attendant liability to pulmonary complications may be avoided.

3. Prevention of Myocardial Failure.—Preoperative digitalization should be reserved for those patients who have auricular fibrillation or cardiac decompensation. As soon as either of the latter two complications are discovered, the patient should receive digitalis immediately. Oxygen therapy is of value in these cardiac complications as is morphine in doses adequate to insure rest. In this way, the failing myocardium is strengthened by the digitalis, the efficiency of the oxygen-distributing function of the heart and blood is increased by the oxygen tent, and the metabolic demands of the organism as a whole are decreased by the morphine to the point where a balance between oxygen supply and demand is struck and cardiac compensation is restored. Blood transfusion is contraindicated in the presence of acute cardiac decompensation, and parenteral fluids should be limited and given very slowly.

Auricular fibrillation should be treated by digitalis until the postoperative reaction has subsided. Although the administration of quinidine will then usually restore a normal

rhythm, it must be remembered that this is dangerous in cases in which the fibrillation is of long duration and in which there is a possibility that an auricular thrombus may be dislodged when the heart reverts to normal rhythm.

CONCLUSIONS

1. It is easier to avoid the complications that follow thyroidectomy than it is to control them after they have developed.

2. In patients with pulse curves that do not respond to the preoperative routine, in patients with excessively high basal metabolic rates, and in patients who have marked emotional instability or a preoperative psychosis, the greatest danger is from thyroid crisis and specific measures for its prevention should be taken early.

3. In patients with substernal goiter, in patients with preoperative pulmonary or upper respiratory disease, and in the aged, pneumonia is the greatest risk and every means for its prevention should be used.

4. In patients with long-standing hyperthyroidism and in patients with auricular fibrillation, cardiac decompensation or myocardial damage, cardiac failure is the greatest hazard, and specific treatment should be directed to sustain the weakened myocardium.

5. The presence of cardiac complications of old age, or of a substernal goiter increases the operative risk of patients with hyperthyroidism but a history of loss of considerable weight, or the finding of a high basal metabolic rate does not increase the operative risk unless other complications are present.

6. If the weight curve rises and the pulse curve falls satisfactorily in response to the preoperative routine, the post-operative course is usually smooth.

DIAGNOSIS AND TREATMENT OF NOCTURNAL INDIGESTION

C. L. HARTSOCK

THE bedside telephone awakens the tired practicing physician to announce that Mr. or Mrs. Brown or son Johnny is having an attack of severe indigestion. Will the doctor come over immediately because Johnny has been sick all day and they were sure he was going to be better by night but instead the pains are worse; or, "Please hurry, doctor, Mrs. Brown is having indigestion with so much gas she can't get her breath and thinks she is dying"; or Mrs. Brown urges haste because Mr. Brown went to bed not feeling very well and wakened up with an excruciating pain in his stomach and shoulders which won't clear up. Even the incandescent bulb, telephone and automobile have failed to dispel the terrors of the darkness and the conscientious physician knows that he must go. Johnny may have acute appendicitis which will rupture before morning. Mrs. Brown is probably only hysterical but she will not be better until she is reassured. Mr. Brown may have a coronary occlusion or the pain may be caused by gallstones or perforation of an ulcer and the diagnosis must be made accurately and quickly. Delay may mean serious consequences.

The frequency with which such dramatic episodes occur and the knowledge that the arts and resources of the physician are taxed to the limit on these occasions make it necessary that we keep in mind those diseases which may cause nocturnal indigestion as well as safe and adequate therapeutic measures for their relief. Obviously, any form of digestive disturbance can occur at night as well as during the day, but

the purpose of this article is to emphasize briefly certain common diseases of the digestive tract or those which simulate diseases of the digestive tract that are particularly prone to occur during the night.

Indigestion which occurs at night can conveniently be classified in two groups:

1. Those digestive upsets which occur fairly regularly at night but also manifest similar symptoms during the day, and are the result of chronic disease of the gastro-intestinal tract.

2. All those conditions which occur in an acute form at infrequent intervals and often without any previous warning of ill health.

The physician is rarely called at night to prescribe for patients whose symptoms are in the first group because these are not severe. The patient has usually suffered in a similar manner during the day and knows how to relieve the distress or he is not so frightened but that he is content to wait to consult his physician at a more opportune time.

Ulcer.—The best example of this type of indigestion is the characteristic burning, gnawing pain of duodenal and sometimes of gastric ulcer. During the day the pain usually comes on from two to four hours after meals, but frequently at night the pain is delayed until six or eight hours after eating and the patient is wakened between 12 and 2 o'clock in the morning. The same distress is recognized which has been present during the day and relief can usually be secured by eating some crackers which the patient frequently keeps by the bedside or by drinking some milk or taking some alkaline powder. When mild obstruction of the pylorus is present, the stomach gradually becomes overloaded with the accumulated intake of the whole day's diet and the patient must vomit to secure relief. At times, there is no food retention but there is marked hypersecretion so that large quantities of liquid material are eructed and this is commonly called water brash.

Occasionally and more particularly in older patients, the only symptoms of ulcer are those which occur at night. A history of nocturnal pain occurring regularly every night for

several weeks at a time, followed by an interval of relief furnish the most reliable evidence that an ulcer exists. Nocturnal pain of this type usually indicates a more penetrating type of ulcer and one in which the management of the ulcer should be especially well regulated to prevent perforation. When the usual treatment of frequent feeding and the use of alkalines is employed, it is continued only until 8 or 9 o'clock in the evening and this gives an opportunity for the acid to accumulate and cause pain at a later hour. Often sodium bicarbonate or other alkalies which cause a secondary secretion of acid are used in the treatment and when they are discontinued at bedtime, the secretion of acid is even higher than usual, thereby causing the night pain.

When night pain occurs in the presence of an ulcer, this is more difficult to relieve than the periodic postprandial distress that occurs during the day. If it is not relieved by the usual treatment, alkalies and feedings should be continued until a later hour or they can be given during the night if the patient wakes with distress. Preferably, the alkalies should be of the slow neutralizing type such as calcium carbonate, which also has the advantage of not stimulating a secondary rise of acid. Calcium tribasic phosphate is also very good for this reason. I have found that a colloidal suspension of aluminum hydroxide is especially helpful for night pain because it has such a long period of neutralization. A teaspoonful in a full glass of milk at bedtime will control the pain in most of these cases. The patients who have obstruction which is thought to be due to edema and spasm and which will frequently respond to medical management should have nightly gastric lavage until the obstruction is relieved. Sedatives and atropine are also helpful. As long as the nocturnal pain of ulcer resists treatment, it means that the ulcer is in a very active state, no matter how well the patient may feel otherwise.

Spastic Colon.—Another common cause for night pain is found in the spastic, irritable colon. This is manifested by distress low in the abdomen and sometimes by mild or

severe cramps which awake the patient about 5 o'clock in the morning, or are present when he wakes at his usual hour and these persist until the morning meal. A bowel movement sometimes will relieve and sometimes aggravate the pain. The passing of flatus gives relief and this fact is of diagnostic importance. The treatment of this condition is the usual treatment for irritable colon, that is, rest, smooth diet, heat, sedatives, natural regulation of the bowels and the avoidance of laxatives and large enemas. Allergy should be considered as an etiological factor.

Hyperacidity which is due either to nervous excitation or reflex excitation from a chronic appendix or diseased gall-bladder will cause night distress at occasional times but not with the regularity of an ulcer or irritable bowel.

The regularity of occurrence and the time of occurrence at night are valuable diagnostic aids in differentiating these three conditions—ulcer, reflex hyperacidity, and spastic colon, if more precise *x-ray* investigation cannot be employed.

Hydronephrosis.—Hydronephrosis with symptoms referred to the gastro-intestinal tract frequently gives night pain simulating digestive disease and which is due to overdistention of the bladder and renal pelvis. The history of relief after urination is a valuable diagnostic clue.

Hypertrophic Arthritis.—The pain which occurs in the low back region early in the morning and which is due to hypertrophic arthritis is frequently referred to the lower abdominal area and the patient is misled into believing that he has a gastro-intestinal disorder. This type of distress can usually be distinguished by its relation to a back pain and also because it disappears shortly after the patient gets up and begins to move about.

Diarrhea.—Diarrhea which lasts more than a few days and occurs at night usually is of organic rather than functional etiology. Morning diarrhea and postprandial urgency without nocturnal diarrhea are more often due to functional causes.

Causes in Children.—Children are apt to have periods

excitation and fatigue, dietary indiscretions or allergic sensitization to foods.

The emergencies of the night, as those cases included in Group 2 might be called, place a tremendous responsibility on the physician who is called to render aid. The diagnosis must be made quickly and accurately and under adverse circumstances of excitement, fear, and limited facilities. Immediate relief of pain is demanded by the patient and relatives, although from the physician's standpoint, the relief by morphine often means masking the symptoms and consequently the correct diagnosis. Decisions based upon flimsy evidence and hasty observation must be made with confidence when the physician knows that the life of the patient may depend upon this decision.

The important problems facing the physician in these emergencies are to relieve the patient without endangering his future chances of recovery, to decide on the advisability or inadvisability of surgical intervention, to suggest a consultant if deemed advisable, to plan a course of therapy and observation when the acute emergency has passed and lastly, to allay the fears and anxieties of the patient and his relatives.

The acute conditions which might be called indigestion are so numerous that it obviously is impossible to describe them in detail and many will even escape mention. Such conditions as perforated ulcer, acute pancreatitis, acute appendicitis, intestinal obstruction, strangulated hernia, ovarian cyst with twisted pedicle, ruptured ectopic pregnancy, etc., are mentioned only to point out that the symptoms and signs should cause them to be recognized as acute surgical conditions, the correct diagnosis often being in doubt until after the exploration. The constant demand by our surgical colleagues for the early recognition and exploration of the acute abdomen makes it unnecessary to discuss these problems here. Certain other conditions which occur more frequently and are typical of acute nocturnal indigestion will be discussed more fully.

Gallstones.—The gallstone has a habit of wandering into

the cystic duct during the early hours of the morning. The typical attack is easy to diagnose, but at times the first attack may be more baffling. No matter how atypical the attack, the signs and symptoms rarely suggest the acute surgical abdomen, and it is usually advisable and safe to administer a hypodermic of morphine in a liberal amount. If relief is not obtained by at least the second dose of morphine, one should begin to question the nature of the trouble. Even when gallstones are known to be present, serious complications should be suspected if relief is not prompt following an adequate amount of morphine. It has been my observation that many physicians are prone to try simpler remedies in an endeavor to relieve the attack without resorting to morphine. If the diagnosis seems reasonably certain, there is no sound reason for withholding morphine. The relief is prompt, the stone is passed and there is much less chance for the development of complications.

Coronary Occlusion.—A condition that must constantly be kept in mind when the physician is called at night, especially if the patient is a man past forty years of age, is coronary occlusion. Patients almost always consider this as acute indigestion, but this condition demands more than the average diagnostic acumen to differentiate it from some of the upper abdominal emergencies. The onset is frequently associated with mild digestive symptoms during the day and early evening which culminate in the severe attack during the night. The frequent occurrence of these symptoms in the male, the prostration, character, location and distribution of the pain, the fall in blood pressure and at times, a friction rub should serve to clarify the diagnosis in the great majority of cases. However, mild attacks are the most confusing. This is unfortunate because if these attacks could be recognized early and proper therapy established immediately, the lives of many men just reaching their prime could be prolonged for several more useful years at least.

Absolute rest and plenty of morphine to relieve the pain is imperative at the time of the attack. The subsequent treatment can be found in any discussion of coronary occlusion.

There is one type of indigestion which occurs almost exclusively at night, but so far as I know, has never been given a satisfactory name although it is a definite clinical entity and is responsible for a large percentage of the emergency calls at night. The usual telephone message is to come at once, someone is dying. If the doctor has had a previous experience with the same patient, he need not be in such a great hurry. The story is practically the same in every case. The patient, usually a woman of any age, is awakened with a great pressure around her heart. She is unable to get her breath, the heart is racing wildly, the hands and feet are numb and there is a sensation and fear of impending death. Shortly after the physician arrives, examines the patient and gives a few words of reassurance, there is a remarkable improvement. If the physician is of the type that inspires confidence, the attack is soon over. The day preceding this attack has usually been an exciting, fatiguing one for the patient, and the attack is a combination of nervous indigestion, hysteria and panic. If the physician who is called to attend such a patient does not wish to have his rest interrupted frequently, he should take measures to prevent similar episodes, which usually become quite regular after the first attack. A spastic colon is usually the cause of these attacks. The spasm of the descending colon causes a gaseous distention of the splenic flexure and the vagus and sympathetic nerves of the heart and respiration probably are stimulated by reflex action. Treatment for a spastic, irritable bowel should be instituted with smooth diet, rest and heat to the abdomen after meals, especially the evening one, the establishment of regular bowel elimination without the use of laxatives and enemas and the use of a mild sedative and belladonna or atropine in some form.

If, in her first few attacks, the patient has been so unfortunate as to secure the services of a physician of the alarmist type, fear often becomes so deeply rooted that in spite of the best treatment, the patient may become a semi-invalid for the rest of her life. Therefore, it is most important for the physician to inspire confidence in the patient and thus relieve

her fear. If the patient does not respond to this psychotherapy in her first attack, the symptoms generally will subside promptly after the use of heat and massage to the extremities, or a warm bath. A quick-acting sedative will usually induce sleep and the doctor may go home not impatient at being called out because of an hysterical woman, but rather with the feeling that, if he has handled the situation well, he may have been responsible for preventing invalidism just as completely as though the attack had been due to some organic disease.

Ptomaine Poisoning.—Severe abdominal cramps accompanied by diarrhea are often the presenting symptoms that demand a night call. The presence of diarrhea is a fairly reliable clue that the lesion will not require surgical intervention. In the presence of severe ptomaine poisoning, the patient may, however, become quite rapidly dehydrated so that severe prostration results and at times urgent treatment is required. The temperature may fall rapidly to a very low figure so that much artificial warmth is essential. Infusions of glucose and saline may be necessary. I have never felt that the time-honored castor oil therapy was a logical or safe treatment even in the mild cases. Complete starvation and opium sedation has always given quicker and better results in my experience.

Renal Colic.—Renal colic should only be mentioned in a discussion of nocturnal indigestion because it often simulates disease of the digestive tract and when it occurs on the right side, it is especially hard to differentiate from acute appendicitis. In cases where differentiation is difficult it is important to make a microscopical study of the urine before a too hasty operation is advised.

With this brief review of a few of the many possible causes of acute nocturnal indigestion, we may simplify the subject somewhat if we approach these difficult problems by trying to place the cases in one of the following groups:

Group I.—Those patients who can be given complete relief from symptoms quickly and at the moment, until a more

accurate diagnosis can be made at a time far before that of this group are those with such diseases as gallstones, biliary colic, pylorospasm.

Group II.—Those patients to whom it is of greatest importance to give immediate relief and treatment of symptoms. These patients require very close and possibly constant observation during the entire duration of the illness. Coronary thrombosis, severe alcohol poisoning, massive hemorrhages from the gastrointestinal tract, suspected poisoning fall in this group.

Group III.—Those patients in whom there is great possibility of an acute surgical abdomen. These patients should be hospitalized immediately and temporary relief given only if absolutely necessary so that the symptoms may not be masked. Further diagnostic measures such as examination of the blood and urine and a plain roentgenogram of the abdomen should be made immediately on arrival at the hospital. A flat plate of the abdomen gives invaluable information in such conditions as perforated ulcer and intestinal obstruction.

Group IV.—Those patients whose symptoms are due to purely functional causes, but to whom the physician should give a great deal of attention during the attack in order to avoid implanting further fears. When such a condition is suspected, the examination should be more careful than usual, which in itself is very calming to the patient, and it is also advisable to follow this examination by a more detailed study at the earliest convenience. Such procedures frequently will cut short what may prove to be a long, distressing episode in the patient's life and a source of considerable worry in the doctor's life.

Group V.—Those patients in whom the symptoms are too indefinite to classify into any one of the above groups but who can be safely but closely watched until the diagnosis is more clearly established. Personally, I prefer to hospitalize these patients but frequently this is difficult and many factors must be taken into consideration, not the least of which is the close attention the physician is able to devote to observation of the patient.

In conclusion, a simple classification of nocturnal indigestion has been suggested in which two distinct groups are pointed out, and in the latter group, which calls for the most accurate and difficult decisions a doctor has to make, five further subdivisions have been made. Certain therapeutic principles have been discussed.

This classification, even though it is based upon the most indefinite, pathological and diagnostic criteria, has helped me approach these problems with greater ease, less worry, and better results to the patient.

THE TREATMENT OF SPLANCHNOPTOSIS

JOHN TUCKER

GENERAL CONSIDERATIONS

As a general rule, those people who have inherited the tall spare conformation of the body possess abdominal organs that lie below the normal position. However, the circulation may or may not be disturbed by symptoms of ill health, although very frequently such anatomical variations are accompanied by lack of ability to withstand a prolonged period of stress and strain, whether it be mental or physical. When a severe illness is experienced, a childbirth or a period of unusual worry in business or in the home, many symptoms appear which may lead to a greater or a lesser degree of invalidism.

CLASSIFICATION

The congenital form with which we are chiefly concerned in this discussion is divided by Cawadias¹ into four distinct groups:

(a) The syndrome designated by Stiller as the constitutional type. Other writers have described it as the linear type, the microsplanchnic or hypovegetative constitution. In these patients the thorax is usually longer than the abdomen, it is narrow in width and shallow in the antero-posterior diameter. The subcostal angle is acute, the heart is vertical and the diaphragm is low, all of which conditions produce diminished capacity in the upper abdomen. Other mechanical features which contribute to splachnoptosis will be considered later. In many instances the ptosis does not affect all the abdominal organs to an equal degree. There may be gastropptosis, with or without ptosis of the duodenum. Likewise, nephropptosis may be accompanied by ptosis of the right colon, or on the

other hand, the major symptoms of distress may be caused by a general coloptosis.

The symptoms may vary in different patients, but the majority are disturbed by dyspepsia, constipation and nervous instability. Various other symptoms such as menstrual irregularities, low blood pressure, and chronic fatigue with hypometabolism may suggest an endocrine factor in the etiology. Many patients show allergic sensitivity and low resistance to infections, especially of the respiratory tract. This picture is familiar to all physicians who are in clinical practice.

(b) A second group is described by Adler² in which the anatomical features of splanchnoptosis are accompanied by symptoms of excessive nervousness. There are frequent headaches, brooding and depression even to the point of melancholia. The appetite is capricious, the bowels are habitually constipated and the "cathartic habit" is well established. The constitutional inferiority of these patients is evident in early childhood. They are the *prima donnas* of their family. They must be spared any worry or shock, and the household activities are modified according to their wishes, thereby establishing a vicious circle, which may lead to neurasthenia or chronic invalidism. It is much easier to obtain satisfactory therapeutic results if these patients can be studied and treated before the period of puberty is over.

(c) The third type or Glénard's disease is characterized by a more severe form of visceral displacement. In this form there may be symptoms such as are seen in Dietl's crisis, pylorospasm, and duodenal stasis. The common symptoms are headache, vomiting, anorexia or severe abdominal colic. In the presence of severe coloptosis, there may be obstinate constipation or symptoms suggestive of chronic appendicitis. It is usual for such symptoms to disappear when the patient lies down in a horizontal position.

(d) A fourth type is described as organic gastro-enteroptosis in which perivisceritis with multiple adhesions occurs. This condition may follow a surgical operation or simple

colitis. The symptoms consist of more severe abdominal pain and there are greater digestive disturbances which are relieved by lying down. The acquired form of splanchnoptosis which may follow a wasting illness, or which may result from pregnancy, the removal of ascitic fluid, a large abdominal cyst or a tumor is probably of this type.

Before we can discuss the treatment of splanchnoptosis with any degree of intelligence, we must have a clear understanding of the anatomical or mechanical features which maintain the abdominal organs in their normal position. We believe that the following are the most important factors:

1. Adequate capacity of the upper abdomen. The abdominal organs cannot remain high unless there is sufficient space. In a normal person the cavity resembles an inverted pear with the larger end uppermost. The subcostal angle is wide, the sternum forward and the diaphragm relatively high.
2. Negative intrathoracic pressure of a sufficient degree so as to exert a pull on the diaphragm when it is relaxed as in expiration.
3. A strong pelvic floor to support the viscera.
4. Strong abdominal musculature with sufficient tone to withstand the inspiratory downward push of the diaphragm, and to lend normal support to the viscera even when filled with food.
5. Retroperitoneal or perirenal fat of sufficient quantity to serve as a support and proper resting place for the various organs. In addition to this, the omentum should possess plenty of fat.
6. Firm and strong attachment between the organs and the diaphragm and the posterior abdominal wall.
7. A proper body posture which is erect and without either lumbar lordosis or dorsal kyphosis.

TREATMENT

Satisfactory results in the treatment of splanchnoptosis cannot be attained unless the physician is really interested in the problem and unless the patient is willing to modify his

habits of living to conform with the therapeutic principles outlined below. Contrary to the opinion of many authors, we believe that the patient should be given a careful and intelligent explanation of his problem. If this is followed by adequate treatment, the results are generally satisfactory. Some of the important therapeutic measures will be discussed in detail.

1. **Diet.**—Disturbed digestion is a most common complaint of patients who have splanchnoptosis. These symptoms may consist of anorexia, heartburn, heaviness in the stomach, vague aches and pains within the abdomen or postprandial vomiting. As a rule, the emesis brings only a small part of the meal. In a few instances, gastro-intestinal hypermotility causes excessive hunger. This vagotonic syndrome can be determined in part by roentgen studies of the gastro-intestinal tract. Not infrequently we find cardiospasm, pylorospasm or a spastic descending and sigmoid colon. In such cases, relief may be obtained by the administration of from 10 to 12 drops of tincture of belladonna one-half hour before meals. The patient's tolerance to this drug will determine whether the amount should be increased or diminished. If the Ewald test meal shows a high free acidity, we may prescribe an alkaline powder, such as equal parts of calcium carbonate, bismuth subcarbonate and the heavy oxide of magnesia, which is given in doses of $\frac{1}{2}$ teaspoonful in water one-half hour after meals. If the acidity is low, and this frequently happens, we give $\frac{1}{2}$ teaspoonful of dilute hydrochloric acid in a glass of buttermilk or fruit juice with meals. In a few cases, food allergy can be demonstrated by skin tests or by the study of a food diary, the latter being kept by the patient. He lists the foods which are eaten at each meal and also records the time at which distress occurs. When these lists are studied with care, an offending food may be found such as wheat, milk, eggs or some less common article of the diet.

When undernutrition seems to be responsible for the trouble, we prescribe a well-diversified diet, which is high in vitamins and calories. This includes meat at least once a day, one

or two cooked eggs, milk, cream and butter, one fruit and one cooked vegetable (one of which is green—broccoli—and the other yellow—provitamin A), fresh and cooked fruits as desired, soups, cereals, breads, nuts and simple desserts. If the colon is spastic, excessive roughage is not desirable and therefore corn, bran, tough vegetable fiber and foods containing seeds are omitted. Milk or cream is taken midway between meals provided it does not destroy the appetite for the next meal. Light wines and beer are usually tolerated well and may serve as appetizers. Many foods should be avoided, and especially is this true of twice-cooked meats and food cooked in deep fat, pickles, olives, highly spiced food, sausages and cold meats, and canapés. Weak coffee or tea taken in moderation rarely causes distress.

When the condition is complicated by a peptic ulcer, diabetes, food allergy or other diseases which require special diets, these must be followed of course, but, if possible, they should be planned to produce a steady gain in weight to a normal or slightly above normal figure.

In certain cases, it may be necessary to give 10 units of insulin immediately before one or more meals, usually the noon meal, in order to create an appetite for food. A bitter stomachic such as *nux vomica* or tincture of gentian is useful in some patients. The meals should be eaten slowly, in a pleasant environment and with a pleasant companion or with music if desired. It is interesting to observe how much these well-known procedures may contribute to good digestion. If the patient is overtired, a rest of one-half hour before eating increases the appetite. Every reasonable measure should be employed to obtain a gain in weight; otherwise, we will fail to secure satisfactory results. At first, three or four weeks may pass before an upward trend in weight begins.

2. Vitamins.—Even though the diet which is prescribed may contain sufficient quantities of the necessary vitamins for a normal person, it is well to give extra quantities, especially for the first few months. Many deficiency symptoms such as anemia, the smooth or atrophic tongue, spoon nails, nervous

irritability and nerve root pains occur frequently enough to justify special measures. Cod liver oil is most helpful if the patient can take it without distress; if not, then cod liver or fish oil concentrates are used as a second choice. If the oil is given, 1 tablespoonful is taken once a day or $\frac{1}{2}$ tablespoonful morning and evening. This will supply the vitamins A and D.

Vitamin B is given in the form of wheat germ, brewer's yeast, or various extracts from rice polishings, yeast or cereal germ. Many excellent preparations of vitamin B are on the market, and proper doses of any of these can be prescribed after each meal. Adequate amounts of vitamins C and E are present in fruits and vegetables. When the body weight has reached the normal for the patient's age and height, the complementary use of vitamins can be diminished in amount or discontinued.

3. **Constipation.**—As a rule, a roentgenogram of the colon shows spasticity throughout its entire extent or more frequently, there is spasm in the descending and sigmoid colon. This will be helped by the belladonna already prescribed, but additional measures may be necessary. It is our custom to advise the following procedures which may be used entirely or in part.

(a) Two glasses of warm water on rising in the morning. A pinch of salt or lemon juice may be added if desired.

(b) Postural exercises (given below).

(c) Gentle deep massage of the abdomen beginning over the cecum and following the course of the colon. This is done before the patient leaves his bed.

(d) A glycerin suppository when the patient rises or an enema of 1 pint of warm water after breakfast. These measures are used for a few days only, and may serve to develop the habit of a daily evacuation before the day's work begins.

(e) A tablespoonful of mineral oil night and morning. This may be taken with 1 or 2 teaspoonfuls of flake agar-agar, or if one prefers, the agar-agar may be taken with or immediately after meals.

(f) When laxatives are required, we prefer from 1 to 4 teaspoonfuls of a saline such as sodium phosphate, sodium or magnesium sulphate before breakfast, once or twice a week. If the bowels are spastic, cascara or phenolphthalein should be avoided since they tend to stimulate a colon which is already hypertonic.

4. **Rest.**—Both physical rest and mental relaxation are important and essential parts of the treatment. It is rarely necessary to prescribe continuous rest, but rather it should be advised whenever fatigue is noted. At the beginning of treatment, a week of quiet rest in bed may relieve excessive fatigue and exhaustion, but it should not be continued too long, because overresting may be enervating. We advise the average patient to remain in bed for ten hours at night but to arise not later than 9 A. M. If sleep is slow in coming, a glass of warm milk or a warm bath before retiring induces quietude and peace of mind. In other cases, these measures produce wakefulness. A short period of reading in bed, if the light is good and the story simple, may soothe the nerves and calm the mind. Such a luxury should rarely be denied these patients. If a drug is needed, at least for a few nights, 30 grains of bromide and 5 grains of aspirin are usually effectual.

5. **Psychotherapy.**—The home environment of patients who suffer from the nervous manifestations of splanchnoptosis is often unfavorable. The husband and wife may be temperamentally incompatible, and most frequently this centers about sex matters. The loss of sexual libido or impotence may be brought on by endocrine dysfunction, excessive physical and nervous fatigue, painful intercourse, fear of pregnancy or many other factors. In unmarried patients, much importance must be attached to an absence of normal sexual gratification. These matters should be brought to light by a frank and kindly discussion with the single patient or in married patients, a conference with both husband and wife. One should attempt to correct any deficiency in the endocrine functions so far as is possible. We have no satisfactory solution for this problem in the unmarried young people. If the normal sex

instinct can be sublimated into other channels, especially in social work among children, there is less nervous tension and increased happiness.

Adler has described many of these nervous symptoms, and he states that the psychological conflict may express itself in organic language. The sufferer is beset by fears about himself and overanxiety about the family. He may experience continuous or intermittent headaches; he may brood over his ill health; his social activities are lessened; the diet is restricted; he loses more weight and he feels more despondent. This form of psychophysical inadequacy may have existed since childhood, or it may have appeared at puberty, marriage, the menopause or following great emotional distress.

It is impossible for us to discuss the psychotherapeutic measures which should be employed. It is our work to discover the important mental conflicts and to attempt to adjust them by wise counsel. It is not enough to tell the patient to "buck up" and pull herself together. She has known for many years that she is nervous. The family physician can often evaluate the situation much better than the psychiatrist, if the doctor will but take the time and the interest in the environmental and physical factors. The problem, at best, is most difficult.

6. **Physiotherapy.**—(a). Ultraviolet light treatments are of some value as general tonic measures. We do not urge this therapy unless it can be arranged conveniently.

(b) Sinusoidal current to the abdomen once or twice a week may give better tone to the right colon. It should be discontinued if it produces abdominal distress or fails to produce better digestion or more satisfactory bowel movements.

(c) Colonic irrigations are not advisable as a regular procedure. In a normal person, the colon is not empty, and to attempt to keep it that way interferes with absorption and motility. It is possible, also, that a series of such treatments may disturb the defenses of the mucosa against absorption of toxins and bacterial invasion. We do not decry its use in ex-

ceptional cases of obstipation but we do condemn the frequent and regular use of the so-called "high irrigations."

7. **Postural Exercises.**—This is one of the most important and valuable forms of treatment for splachnoptosis. It is effective in the majority of patients if it is carried out regularly and with the proper technic. It makes very little difference whether the patient is suffering from nephroptosis, gastroptosis, coloptosis or a descensus of all of the abdominal organs. This procedure has many advantages; it produces deeper breathing, better oxygenation of the tissues, a greater capacity for the organs in the upper abdomen; likewise, it develops the intercostal muscles and also the muscles of the diaphragm and abdominal wall.

This method of therapy has been elaborated by Goldthwait³ who has demonstrated that a patient with enteroptosis nearly always has a faulty posture. A profile view of the patient will show lumbar lordosis and dorsal kyphosis. The use of exercise and proper muscle training tends to correct this deformity by flattening the lower back and by bringing the head erect and the chin back. A detailed discussion of these measures is contained in the manual of Posture Exercises prepared by the Children's Bureau of the U. S. Department of Labor, Publication No. 165. A method of procedure is as follows:

(A) In lying position, on a firm bed or on the floor.

1. Deep breathing.

(a) Raise the thorax as high as possible during inspiration.

(b) Hold the ribs in raised position and breathe by moving the diaphragm up and down.

2. Pelvis tilting: keep the abdomen down and at the same time, tilt the pelvis forward and then backward, this tends to flatten out the lumbar curve.

3. With the pelvis tilted forward, draw each leg up and down with the heel close to the bed. In this exercise the knees are flexed and extended.

4. With the pelvis tilted forward, raise the head up and down.

5. With the pelvis tilted forward, raise each leg alternately, with the knees stiff.

6. Turn to the knee-chest position on the bed and kick out with each foot as high as possible. This is done with alternate feet and tends to bring the organs forward and to the upper part of the abdomen. If this exercise is taken before retiring, the patient can then slide down and sleep on the abdomen.

7. If the patient sleeps on the back, place a folded pillow under each knee and one under the buttocks; this flattens out the lumbar curve. If he sleeps on his side, keep the knees and hips flexed.

(B) Standing position:

1. With the pelvis tilted forward, flatten the back against the wall.

2. With the back flat, walk away from the wall, raise up and down on the toes and return to the wall.

3. With the back against the wall, raise alternate legs first with the knee flexed and then with the knee straight.

4. Practice alternate stooping and standing with the back flat and the chin back.

These exercises should be repeated several times at each session and should be done morning and evening.

Abdominal belts or supports need not be used in the thin patient with splanchnoptosis if he will practice his exercises faithfully. It is very much better to develop the musculature and correct the postural defects than it is to attempt mechanical lifting and support of the viscera. In obese people with pendulous abdomens, the musculature may be so weakened that a corset or belt is necessary for support. The chief requirements of a satisfactory support is that it be comfortable and that it will exert an upward pressure. The majority of patients obtain better results without mechanical appliances. We do not believe that it is necessary to have the foot of the bed raised during sleep.

8. **Surgery.**—The chief indications for surgery are as follows:

(a) Repair of the pelvic floor when there is marked pro-cidentia.

(b) Suspension of a floating kidney when there is intermittent hydronephrosis or Dietl's crisis and when the exercises and abdominal support fail to relieve the condition.

(c) Suspension of the hepatic flexure when this is excessively low and when other measures fail to restore it to the normal position.

(d) Removal of congenital veils and bands when these interfere with normal gastro-intestinal function.

As a rule, patients who suffer from splachnoptosis fail to derive benefit from surgical operation unless it is performed to correct a definite and recognized abnormality such as those noted above. And yet, how often do we see multiple incisional scars on the abdominal wall which were made for removal of supposedly diseased appendices or for pelvic operations?

SUMMARY

In the modern treatment of splachnoptosis, a careful study of the patient must be made from many angles. We must consider the psychological factors, the nutrition, the musculature, and the posture. Our instructions should be explicit and if possible written out so that the treatment can be understood easily. When verbal instructions are given, the patient becomes confused. Much of a knowledge of the art and science of medicine can be used in the management of these unhappy people by giving them encouragement and sympathetic understanding.

INTESTINAL TOXEMIA

JOHN TUCKER

CONSIDERABLE doubt exists in the minds of many able observers that chronic intestinal toxemia is a true clinical entity. The safeguards supplied by nature in the intestinal mucosa, lymph supply and liver appear to be quite adequate for the protection of the body against the ordinary chemical substances, the usual products of putrefaction, or the fermentation activity of intestinal bacteria. No one questions the fact that acute gastro-intestinal upsets may result from the ingestion of spoiled or contaminated foods, whether the primary reactive agents be chemical or bacterial. However, what diagnosis may one make for a rather large group of patients who are disturbed periodically or intermittently by "bilious" spells which are characterized by constipation, flatulence, physical fatigue, mental lethargy, insomnia, anorexia, furred tongue, foul taste and headache? Our colleagues of a preceding generation treated a vast number of these patients, and they were honest in their belief that these symptoms were due to intestinal absorption as the result of constipation or auto-intoxication. More recently, however, if we consult the most up-to-date and generally accepted classification of diseases,* we will find under the general heading of "Diseases of the Intestines" the diagnostic term, "Intestinal Intoxication due to Putrefaction of Ingested Food" and again under "Disorders of Carbohydrate, Fat and Water Metabolism," the term "Intoxication. Acute Intestinal" occurs. This list of diagnoses was compiled by various committees representing the leading medical groups of this country and includes both chronic and acute intestinal toxemia.

* Standard Classification of Nomenclature of Diseases.

It is quite apparent that the function of the intestinal tract involves a complex mechanism. Among the requirements for normal alimentary activity are a stable nervous system, normal appetite, proper food, efficient digestion, normal motility and as a rule, regular evacuation from the colon. When we attempt to determine what is wrong with the patient who has a serious disturbance of this mechanism, it is also obvious that we must not be influenced unduly by a group of symptoms, but the diagnosis must be based upon a careful study of the patient's life history including his emotional reactions and eating habits as well as the objective evidence secured by careful physical examination, roentgenograms and laboratory data. These routine investigations are essential in eliminating from the diagnosis such organic diseases as chronic cholecystitis and cholelithiasis, peptic ulcer, carcinoma, chronic appendicitis, and lesions of the central and peripheral nervous systems as well as lesions of the lungs and genito-urinary tract. Any patient who has suffered with recurring attacks of digestive upsets, whether or not they have been of the bilious type, is entitled to such an examination. Most of the mistakes in diagnoses are the result of inadequate study rather than the result of professional ignorance.

From a scientific viewpoint, we are unwilling to accept the diagnosis of chronic intestinal toxemia associated with constipation until the following questions have been answered.

1. Does experimental evidence indicate that toxic substances can be absorbed from the intestinal tract as the result of putrefaction, fermentation or constipation?

2. If toxic materials or bacteria do penetrate the "intact" intestinal mucosa, can they overwhelm the defensive mechanisms of the body?

3. Can the symptoms described as "bilious" be explained by some disturbance other than the absorption of toxic products?

Many articles pertaining to intestinal toxemia have appeared in the literature, but most of them have dealt with the clinical rather than the experimental aspects of the subject.

In recent years, however, most important evidence has come from the research laboratories. Alvarez¹ has reviewed the experimental work on this subject and cites the following possible sources of intestinal poisons, using the classification given by Weintraud and by Wells:

1. From constituents of the digestive secretions.
2. From the products of normal digestion.
3. From the products of putrefaction and fermentation.
4. Synthetic products of bacterial activity in the bowel.

From the available evidence, he concludes that neither the constituents of the digestive secretions nor the products of normal digestion are able to produce any recognizable toxic symptoms. Many substances which may appear during the normal course of digestion such as the amino-acids, ammonia, hydrogen sulphide, volatile fatty acids, acetone or oxalic acid may play some part in temporary gastro-intestinal upsets such as diarrhea, yet they fail to give rise to any general symptoms of toxicity. A possible exception exists in the factor of food allergy, which will be discussed later.

Many chemical substances may form in the bowel from the putrefaction of proteins. These include indol, skatol, indol acetic acid, phenols, cresols, histamine, tyramine, choline and methylguanidine. In all instances, the evidence would appear to show that insufficient quantities of these toxins can penetrate the intact bowel wall or escape the detoxifying action of a normal liver to produce general symptoms. However, we have been taught for several generations that the amount of indican in the urine is a measure of the degree of intestinal putrefaction. In regard to this, Alvarez makes the following statement: "As Hale White says, there is no doubt that an excess of indican is often associated with serious intestinal disturbances and with conditions suggesting auto-intoxication, but we know also that many people pass large amounts of indican for years and yet remain in good health. Furthermore, large numbers of constipated people show no increase in the indican in their urine.

"We see then from all this, that although indol has toxic

properties and although it can produce in man some symptoms similar to those observed in the constipated, it must not be forgotten that some of those symptoms do not correspond to those observed clinically; and what is more important, experiments have been done with doses enormously greater than those met with even in the presence of disease." Pertaining to this point, there is another observation that even though feces normally contain 60 mg. of indol per 100 Gm. of fresh material, it appears evident that little of this is absorbed since only 6 to 20 mg. are excreted in the urine in the form of indican.²

In a similar manner, we can dispose of pressor substances, tyramine and iso-amylamine, which are assumed to exert some influence in the maintenance of high blood pressure. Likewise, in the case of histamine which has a depressor effect and tends to lower blood pressure, the absorption is too little to tax the detoxifying function of the liver.

The fourth hypothetical source of intestinal toxins exists in the products of bacterial activity within the bowel. It has been stated that approximately 46 per cent of the total nitrogen of feces comes from bacteria.² However, most of the bacteria found in the normal excreta are dead and harmless. They have been alive and active in the fluid contents of the cecum and ascending colon, but die as fluid is abstracted during the passage of the stool toward the rectum. The normal flora seem to be friendly toward the human host by discouraging the growth of pathogenic bacteria. The common bacteria of the colon produce very little exotoxin and scarcely any endotoxin. It is believed by most authorities that the pathogenic bacteria and protozoa are harmless so long as they are unable to attack the intestinal mucosa and produce larger or smaller ulcerations. Where ulceration occurs, diarrhea rather than constipation is usually found. We must acknowledge the fact that bacteria have been found in the lymph nodes of the mesentery in instances where gross ulcerations of the bowel have been lacking. However, it is very doubtful whether any symptoms appear unless the body resistance is lowered to the point where

the defense mechanisms are inadequate to destroy these bacteria as they invade the blood stream and other organs. The symptoms, then, are not those usually considered to be associated with intestinal toxemia but rather the symptoms are those we consider to be associated with such clinical entities as pyelitis, arthritis and lymphadenitis.

The evidence presented thus far has failed to show satisfactorily that the symptoms ascribed to constipation, biliousness or auto-intoxication are due to intestinal absorption. We believe that several other factors in this problem are of much greater significance:

1. Nervous disturbances.
2. Abnormalities of gastro-intestinal motility.
3. Allergy.

The profound effect of the emotions on gastro-intestinal functions has always interested our profession. The patient who has been symptom-free suddenly is brought face to face with a serious emotional crisis—the loss of a loved one or the devastating effect of disaster. He may experience all the gradations of anxiety and fear, even to despair and melancholia. During this cycle, the bodily functions undergo marked disturbances, and digestion and elimination are upset. In the acute phase of the anxiety, there is loss of appetite, a dry mouth, bad taste, rumbling in the bowels, often mild or severe abdominal cramps and diarrhea or constipation. Later, as the psychic trauma continues, the anorexia remains, the tongue becomes heavily coated, the patient is fatigued, body aches develop and head pains, dizziness, constipation and all the symptoms of biliousness color the picture. In such instances, it is difficult to explain all the mechanisms which are effective. We feel reasonably certain that for a time at least, there is inhibition of digestive ferments, probably inhibition of bile formation and most important, disturbances in gastro-intestinal motility. In such an hypothetical case, we have very little reason to suspect that intestinal toxemia is a matter of any moment. Likewise, it seems that in nervous shocks, similar disturbances of less severity are set up which, in sensitive peo-

ple, produce a chronic malfunction of the digestive tract and the symptoms of chronic intestinal toxemia result. This phase of the problem is discussed in interesting detail by Alvarez.³ Very frequently, patients are unwilling to accept as a fact the functional origin of their trouble, because their point of view is colored by the blatant radio advertising of nostrums for the relief of "excess acid," "auto-intoxication," etc. The popular notion that any excretion that smells badly must be poisonous does not extend to some of our most delectable articles of food which may be anything but pleasant to the nostrils. The laity are sensitized to the horrors of intestinal putrefaction and constipation.

Disturbances in gastro-intestinal motility produce the majority of the symptoms of abnormal digestive function. Although this important subject cannot be discussed in any great detail, our experience has shown that many of the bilious symptoms occurring with constipation are the result of a spastic or irritable colon. Many years ago, Sippy drew attention to the disturbing effects of the "irritable" colon and more recently Kantor⁴ and others have described the syndrome of the "unstable" colon. Among the intellectual class of patients, spastic constipation is an exceedingly common finding. Usually, the spasm occurs in the distal descending and sigmoid colon and very often but not invariably this is associated with gastro-intestinal hypermotility up to the point of spasm. Not infrequently the barium meal, which under normal conditions reaches the distal colon in twelve hours, will arrive there in four or five hours, but the defecation reflex does not take place. With this, there is abdominal distress accompanied by cramps, rumbling, occasional expulsion of gas and a heavy or sore sensation in the lower abdomen, especially on the left side. When the stools are passed, they are pencil-like, segmented or formed by a mass of small, elongated or spherical masses. In severe cases, mucus or blood is seen from time to time. Hemorrhoids may occur as a secondary complication. This condition is the result of an hypertonic, autonomic nervous system, which is often styled "vagotonia." The habitual use of cathartics ag-

gravates the irritability of the colon, or it may be the important initiating factor. The use of laxatives containing phenolphthalein, cascara or both are especially harmful, and whether phenolphthalein is taken as such, eaten in candy form or chewed in gum, it still tends to overstimulate the colon.

Everyone has experienced the feeling of well-being that surges over the body almost immediately after a normal bowel evacuation. A similar sense of relief after a copious catharsis comes to the nervous patient who is constipated and has bilious symptoms. By no stretch of the imagination can we convince ourselves that this relief is due to the sudden elimination of toxins; the reaction is entirely too prompt for that. A much more rational explanation appears to be that the overloaded distal colon is relieved of spasm at least temporarily, and that the unpleasant afferent impulses that have been crowding into the optic thalamus are suddenly stopped. There is a sudden feeling of relief and the feeling tone of the body rapidly returns to normal. Unfortunately however, in those people who have acquired the "cathartic habit," the spasm returns in a short time only to be relieved again but less effectively by catharsis. We are inclined to believe that the relief of spasm is of much greater importance than is the mechanical unloading of the bowel. In constipated, nervous patients with insomnia, sleep is often obtained promptly following the use of a small enema of plain water or normal saline solution (not soapsuds) before retiring at night. The relief is mechanical, not chemical.

Relatively little of scientific value can be said in regard to the rôle of allergy in the production of symptoms of chronic intestinal toxemia. The cutaneous and intracutaneous tests for food allergy are of some diagnostic importance, but not in a high percentage of cases. The use of a food diary, if kept properly, will give additional information; however, we must recognize the probability that most normal people are allergic to some food and hence we are at a loss to evaluate many of the positive reactions that occur in patients with gastro-intestinal symptoms. When careful questioning elicits a history of urticaria, hay fever, asthma, frequent colds or other disturb-

ances which are known to be caused by or aggravated by allergy, we may assume with greater authority that the digestive symptoms are allergic in origin. In many instances, the patient knows what foods disagree with him and volunteers the information that "milk poisons me" or "if I eat fish, I am in for a sick headache." Experimental and clinical experience in the future will help to clarify this important subject.

The treatment of the symptoms usually attributed to chronic intestinal toxemia includes many of the measures outlined in the treatment of splanchnoptosis. Attention is especially directed to the care of:

1. Nervous tension.
2. Habits of living.
3. Food and drink.
4. Bowel elimination.
5. Medication.

Treatment of nervous tension will require one or more consultations in which the problems of business, sex and the home are discussed in a confidential manner. No set rules of procedure can be followed, since it is obvious that each patient presents an individual problem. An immediate period of rest or a vacation is frequently imperative. The patient's attention to the details of his problem followed by a clear analysis often will enable him to suggest a satisfactory solution. In such cases, our accumulated experiences in dealing with nervous patients can be utilized to good advantage. Very often, the patient passes from a stage of bewilderment and anxiety to a state of increasing self-confidence. He must be given a clear and simple explanation of his trouble and above all, the clinical examination must be thorough enough to exclude, as far as possible, any organic basis for his complaints. This will do much to reassure the patient.

Instructions regarding habits of living must not be stereotyped but must be designed to conform with the occupation and social status of the patient. It is obvious that the key-stone is temperance in all things—work, play, sex habits, eating and drinking. Aristotle taught us centuries ago that the

temperate life is the happiest and the most satisfactory, and there is no reason why we should deviate from this fundamental principle, even though the patient be a busy executive. Other things being equal, the average man can smoke 6 to 10 cigarettes or 2 or 3 light cigars a day, but it is better to avoid smoking until after the noon meal. Much diversion and relaxation will result if a good hobby is developed. Treatment must be directed so that relaxation and a reasonable tranquility of mind are habitual.

The diet of these patients should be well balanced. In the obese, sugars and starches should be reduced. In the undernourished, a high vitamin, high calorie regimen should be prescribed. In the majority of cases, a smooth, rather low residue diet is prescribed especially for those patients who have the spastic "unstable" colon. When normal bowel regularity is attained, the diet is modified by the gradual addition of more bulky foods containing vegetable fiber. The following smooth diet may be used as a guide:

SMOOTH—LOW RESIDUE DIET

Breakfast:

Orange or grapefruit juice, strained or puréed cooked fruits.

Eggs—one or two.

Bacon (well masticated).

White bread and butter, toast, zwieback.

Any smooth cooked cereal such as farina, cream of wheat, rice, cornmeal or strained rolled oats. Corn flakes, puffed rice.

Lunch and Dinner:

Broths, bouillon, cream soups with puréed vegetables.

Meats, scraped or finely ground.

Beef.

Lamb.

Fresh pork, lean and well cooked.

Chicken and turkey.

Squab.

Fresh fish, not fried.

Oysters.

If meat is tender and is well chewed, grinding may be omitted.

Vegetables:

Puréed vegetables as peas, carrots, asparagus, cauliflower, squash, tomatoes. (Omit spinach, string beans, and beets.) White potato mashed, boiled or baked (no skin).

Bread:

White bread, toast, biscuits cut thin and toasted.

Salads:

Tomato aspic, canned fruit salads (omit pineapple).

Desserts:

Puddings: rice, tapioca, custard, blanc mange.

Jello (plain), junket, ice cream, ices, fruit whips.

Stewed peaches, pears, apricots (well chewed).

Simple cake.

Baked bananas.

Beverages:

Weak tea and coffee.

Kaffee Hag and Sanka coffee.

Boiled milk.

Cocoa.

Postum.

Butter, cream and mayonnaise as desired.

Avoid all highly seasoned foods.

It is important to avoid all foods containing tough skins, seeds, rough fiber and bran.

Do not swallow any food that is not smooth or very well chewed.

When there is reason to suspect food allergy, the foods which seem to give offense are omitted; most frequently these are milk, wheat and eggs. The use of liquids with the meal are permitted in moderation but tea and coffee are prohibited for a time. Alcoholic beverages, with the exception of light wines, are contraindicated. Beer may be tolerated well by patients who have no idiosyncrasy and who find that it is a pleasant stomachic.

The bowel management is well outlined by Kantor.⁴ He states that the frequency of the cathartic habit in the absence of constipation is rather high, and he emphasizes the importance of therapeutic measures directed toward the restoration of normal bowel function. He cites the three R's of successful bowel treatment—reassurance, relaxation and reeducation and he recommends the following procedures:

(a) Withdrawal of all cathartics.

(b) Mild sedatives to promote relaxation and sleep.

(c) Belladonna.

- (d) Bland diet.
- (e) Adequate intake of fluid.
- (f) Lubrication with mineral oil.
- (g) Use of agar-agar.
- (h) The occasional use of koalin or x-ray barium to allay irritation.

In our practice, we usually advise that the mineral oil be used night and morning in 1-ounce doses. Agar-agar is given in the flake form—2 teaspoonfuls after each meal, if it is well tolerated. The dosage is reduced as the condition of the bowel improves.

For medication, we prescribe 10 drops of tincture of belladonna after meals increasing the amount to 12 or 14 drops, until the mouth becomes dry, and then the dose is diminished to three fourths of this amount. To secure relaxation, 10 grains of sodium bromide with 10 minims of tincture of hyoscyamus is used three times a day. It is rarely necessary to use any other drugs unless the bromide produces furunculosis; in such a case, $\frac{1}{4}$ grain phenobarbital is used. Four drachms of tincture of nux vomica and 4 drachms of dilute hydrochloric acid U.S.P. in a 4-ounce mixture taken in a teaspoonful of water before meals will help to stimulate better gastric secretion. In general, however, belladonna or atropine and a sedative are adequate.

Some evidence exists which suggests that mineral oil may carry out some of the important and essential vitamins before absorption takes place. If this proves to be correct, then the use of lubricating oils should be discontinued as soon as the colon returns to normal function.

Much more could be said about the problem of intestinal auto-intoxication and biliousness and the literature contains many articles on various aspects of the disease. When the treatment is directed to a correction of the known physiological disturbances, and when it is based on a careful study of each patient, the results will justify fully the expenditure of time and effort.

DIAGNOSIS OF CANCER OF THE COLON

THOMAS E. JONES

THE insidious manner in which malignancy of the colon begins demands the most painstaking care in eliciting the history and making the examination. Uniformity of signs and symptoms do not occur because they vary according to the location of the lesion in the colon.

In the proper interpretation of the symptoms of which the patient complains, it will be well to remember that because of its embryological development, anatomical variations, and physiological function, the colon differs in its various parts. The right side of the colon (the cecum, the ascending colon and half of the transverse colon) is formed from the midgut. Anatomically, the lumen is much larger, the walls are thinner and the blood and lymphatic supply are very plentiful. From a physiological standpoint, the contents of the right half of the colon are liquid, and absorption of water takes place. The left half of the colon (from the mid-transverse colon to the rectum) is developed from the hind gut. Its lumen is smaller, its coats thicker, and its blood and lymphatic supply is less than that of the right half. The contents of this part of the bowel are solid and its physiologic function is that of storage. Consideration of all these factors will then make it clear that it is impossible to have only one group of symptoms for cancer of the colon.

Cancer of the right side of the colon generally manifests itself in a disturbance of physiologic function. Due to altered physiology, some of the earliest symptoms are weakness, loss of weight and anemia. This occurs long before any mass is palpable. There are no obstructive symptoms because the

contents are liquid, the lumen is large and the growth flat. The patient frequently complains of indigestion and of vague epigastric distress which simulates chronic appendicitis. Constipation is not common, but there may be occasional attacks of diarrhea. In any case of unexplained anemia, the stool should be examined for occult blood and the presence of a carcinoma of the cecum should be considered.

In lesions of the left side of the colon, however, constipation and obstructive symptoms of pain and cramping frequently occur for the reasons mentioned before—since the stool is firm in consistency, the bowel lumen smaller, and the growths tend to encircle the bowel. Because of the proximity to the anus, straining and the trauma of the hard stool, gross blood is frequently seen. A lesion in the sigmoid or rectum, in which location most malignancies of the bowel occur, causes considerable mucous discharge, and there is urgency of bowel movements and so-called “diarrhea.” I believe that this latter symptom leads to a number of errors in diagnosis. The physician too frequently associates cancer with constipation and obstruction, and when the patient complains of frequent bowel movements, the possibility of the presence of malignancy is not investigated thoroughly, and too often the patient is dismissed with a prescription for paregoric. These frequent bowel movements are not due to true diarrhea, but represent emissions of mucous, pus and blood. An examination of the stool makes many a diagnosis for the pediatrician; it will do the same for those who care for adult patients. Even though the patient complains of diarrhea, examination of the stool may convince the physician that further investigation is essential.

Another type of malignant growth of the left side of the colon, which may give a different and rather characteristic picture and one which deserves mention here, is the annular lesion which produces the napkin-ring type of deformity. In its early stage, it involves the muscularis and will produce constriction. Often an acute obstruction is the first symptom noticed by the patient. Occasionally, it is not complete during

the first attack and it may be weeks or months before the patient experiences another attack. This group constitutes, however, a very small percentage of the total cases.

In making the diagnosis of cancer of the colon then, the physician should make the following examinations in the order named: a careful history and physical examination, digital, proctoscopic and sigmoidoscopic examination, and lastly, roentgen examination. When one realizes that from 75 to 80 per cent of these growths are readily diagnosed by digital or sigmoidoscopic examinations, it is quite obvious that roentgen examination should be resorted to only after other simple procedures fail. Furthermore, a moderately early cancer of the rectum may frequently be overlooked on roentgen examination and in advanced cases, filling the colon with barium may precipitate an obstruction which requires an emergency colostomy. Roentgenography is an invaluable aid and I have the greatest respect for it and its usefulness, but it must never be used first to the exclusion of all other methods of diagnosis.

In eliciting the history then, we must inquire carefully regarding the function of the gastro-intestinal tract. Generally one learns that there has been a change in the patient's bowel habits; from a perfectly normal routine, he has noticed some irregularity, or constipation has alternated with diarrhea. Frequently, there will be a feeling of uneasiness or rumbling in the bowel or a sensation of incomplete evacuation. A change in color of the stool or the presence of blood in the stool may have been noticed. Lesions in the cecum generally give rise to discomfort above the umbilicus, while those in the sigmoid give rise to pain below the umbilicus. However slight, these symptoms must be investigated thoroughly. Loss of weight is not a very early symptom.

On physical examination, the color of the mucous membranes must be noted as well as the texture of the skin. The lymphatic glands in the supraclavicular space are palpated for occasionally metastasis may have occurred from a carcinoma of the sigmoid and rectum, although this does not happen as frequently as from a carcinoma of the stomach. Palpation of

the abdomen for masses must be carried out in a routine manner from the sigmoid to the cecum and the liver must be felt for carefully. If the growth is in the lower 2 inches of the rectum or anus, palpable inguinal glands may be found. From a laboratory standpoint, blood studies are particularly indicated.

For the digital examination of the rectum, it will add a great deal to the comfort of the patient if the entire length of the finger is lubricated with K.Y. jelly rather than merely placing a small bit of vaseline on the tip of the finger, as is usually done. The examination is best carried out with the patient bending over a table. By having the patient bear down it will frequently bring in contact with the palpating finger a growth which would not be discovered otherwise. Next in order is a sigmoidoscopic examination preliminary to which it is necessary to have a clean bowel. This may be accomplished by saline laxatives or by enemas. The sigmoidoscopic examination is best accomplished with the patient in the knee-chest position or on a tilt table. After the sigmoidoscope is introduced into the rectum, the plunger should be removed so that insertion from then on is done under direct vision and not pushed up blindly. With the use of air inflation, the scope may be introduced from 10 to 12 inches in most cases; however, this occasionally is impossible due to congenital kinks, bands or inflammatory processes. Force must never be used in manipulating the scope. If a lesion has been demonstrated by this means, biopsy may or may not be taken, according to the experience of the examiner. In case a lesion has not yet been demonstrated, roentgen examination must be made and the patient should be referred to the roentgenologist with some indication as to what the physician expects to find. Too often, the physician orders a certain type of examination which will prove to be incomplete. The roentgenologist should be used as a consultant and should have the liberty of carrying out whatever type of examination he feels is indicated in order to determine the presence or absence of a malignant lesion of the colon.

If all these examinations reveal no abnormalities, the patient should not be dismissed if there is the slightest suspicion that a malignant lesion may be present, because a negative x-ray examination may lead to a false sense of security. The physician should examine the patient at monthly intervals to be sure that the symptoms do not persist, and if they do even with negative findings, exploratory operation should be resorted to in any suspicious case.

In the differential diagnosis of lesions in the right colon, tuberculosis, actinomycosis, and amebic ulceration must be considered. Actinomycosis is quite rare, and tuberculosis is generally associated with pulmonary involvement which may be revealed by x-ray of the lungs. The prevalence of amebic dysentery, which in the last few years has proved to be endemic, frequently may present difficulty, and in cases in which it is suspected, the stool should be examined for amebae. In the left side, amebic ulceration, diverticulitis and endometriosis involving the sigmoid in women must be differentiated. Obstruction without bleeding, the presence of pain and fever and x-ray examination will frequently rule out diverticulitis, while the diagnosis of endometriosis in women is generally made from the history, the disturbance being of long standing, and lower abdominal pain or rectal symptoms being generally augmented during the menstrual period.

DIET IN THE TREATMENT OF ARTHRITIS

RUSSELL L. HADEN

ARTHRITIS is not a single disease but a group of diseases with little in common except joint involvement. Any discussion of diet in the treatment of joint disease must take into consideration the widely different etiologic factors and clinical classes. Clinically, arthritis may be grouped satisfactorily as follows:

1. **Rheumatic fever** in which the cause is unknown. This has been thought to be due to the direct toxic action of bacteria or to the reaction of an allergic joint to bacteria, probably streptococci. Just now there is much data indicating that a filtrable virus may be the causative organism, the activity of which in turn may be initiated by the streptococcus and other bacteria.

2. **Specific infective arthritis** due to joint invasion by specific types of bacteria such as the gonococcus, the staphylococcus, the *Streptococcus hemolyticus*, or the pneumococcus. Here the joint disease represents a metastatic localization in the joint from a bacteriemia arising in an infected focus. This is usually an acute process which may become chronic.

3. **Arthritis due to traumatism** such as the "golfer's shoulder" and "tennis elbow." The joint symptoms are the direct reaction of joint tissue to mechanical injury.

4. **Arthritis Occurring as an Incident in the Allergic State or in Some Constitutional Disease Such as Hemophilia, or in Neurogenic Disease Such as Tabes Dorsalis or Syringomyelia.**—In the allergic state, there is a transudation of fluid into the joint covering or periarticular tissues: in hemophilia, the joint disease is due to hemorrhage

into the joint with consequent cartilage destruction and secondary changes. In *tabes dorsalis* or other neurogenic diseases, there is primary degeneration of joint cartilage probably due to excessive trauma in an anesthetic joint.

5. **Gout.**—This is a metabolic disturbance with protean manifestations. It is primarily a chemical disturbance during the course of which urates are deposited in joint cartilage and the surfaces are much irritated, producing the picture of arthritis. The accumulation may be due to impaired excretion of uric acid or to a difficulty in oxidation in the body tissues.

6. **Chronic rheumatoid arthritis** in which the disease is localized primarily in the synovial membrane and periarticular tissues. The cartilage here may also be involved but always secondarily. This disease is probably closely related to rheumatic fever and the etiology is still unsolved. Even if there is one etiologic agent, the activity of the causative agent is certainly influenced by many factors.

7. **Chronic hypertrophic arthritis** which is due to a primary softening or degeneration of joint cartilage secondary to a disturbance in nutrition of the cartilage. This disturbance is a manifestation of the wear and tear of tissues which may be initiated or influenced by impaired nutrition from any cause, circulatory changes, increased weight bearing, decreased metabolic rate with consequent defective combustion, and various chemical disturbances impairing the integrity of joint cartilage.

It is apparent from this clinical grouping that many cases of arthritis have no relation to diet except insofar as any disease process is influenced by any factor impairing the general health. Thus in specific infective arthritis, rheumatic fever, traumatic arthritis, constitutional or neurogenic arthritis, usually the only indication is for a completely well-balanced diet unless a special diet is indicated for the disease in which the arthritis is an incident. If allergy is a factor, food allergy must be studied and the diet adjusted in accordance with the results of the allergy tests. An anemia often develops rapidly

in rheumatic fever or in arthritis due to specific bacteria, so this should be taken into consideration and foods for the correction of the anemia should be supplied abundantly. These are liver and red muscle meat, fruits which stimulate blood formation—especially peaches and apricots, vitamin C in the form of oranges and grapefruit or iron in the form of prunes and raisins—and the iron-containing vegetables such as spinach and lettuce.

When gout is the only factor, it should be treated specifically by diet in an attempt to decrease the uric acid in the blood and tissues by limitation of the intake of purine-containing substances from which uric acid is formed. Patients suffering from gout are often overweight, so weight reduction is frequently necessary also.

DIET FOR GOUT

Breakfast: fresh fruit, cereals with cream, eggs, bacon, toast, wheat or buckwheat cakes with maple syrup, caffeine-free coffee.

Lunch: vegetable or cream soup prepared without meat stock, eggs, cheese, tomato and bacon sandwich, vegetable salad, ice cream or pudding, milk.

Dinner: vegetable or cream soup prepared without meat stock. Meat substitutes made with cheese such as cheese soufflé and Welsh rarebit, macaroni, rice, potatoes, corn, tomatoes, cabbage, cauliflower, turnips, squash, lettuce, celery, onions, string beans, carrots, broccoli, asparagus, brussels sprouts, bread, fresh or preserved fruits, vegetable salads with French or mayonnaise dressing, cottage cheese, puddings made with rice or tapioca, nuts, ice cream, milk, weak tea, or caffeine-free coffee. The following foods should be avoided: sweetbreads, liver, kidney, herring, sardines, anchovies, bouillon, sea foods, poultry and other meats, spinach, peas and beans.

If the patient is overweight, a 1000-calorie diet should be satisfactory. Such a diet selected from the above list would be:

Breakfast:

Fruit	1 serving
Egg	1
Toast	1 slice
Butter	1 square
Caffeine-free coffee	As desired

Luncheon:

Cream soup, with:

Milk—whole	$\frac{1}{2}$ glass
and	
Vegetable	$\frac{1}{2}$ cup
Vegetable—cooked	$\frac{1}{2}$ cup
Vegetable—raw	1 cup
Butter ..	1 square
Milk—skimmed	1 glass
Fruit ..	1 serving

Dinner:

Cheese	2 ounces
or	
Eggs	2
Vegetable—cooked ..	$\frac{1}{2}$ cup
Vegetable—raw ..	1 cup
Butter ..	1 square
Milk—skimmed	1 glass
Fruit ..	1 serving

Chronic rheumatoid (atrophic) arthritis has little in common with degenerative arthritis described below except joint involvement. Here the patient shows evidence of a generalized disease as indicated by loss of weight, multiple joint involvement, anemia, malaise, and disturbed circulation. The joint picture is that of an inflammatory disease. So far, no one causative agent has been discovered. All the evidence indicates that an infection is concerned in its etiology but that the cause is influenced by numerous factors. Careful studies of well-developed cases show frequently a marked anemia of the iron deficiency type, an achlorhydria, some variation from normal in the metabolic rate, a diabetic type of glucose tolerance curve, sometimes an excess of uric acid, a redundant colon possibly due to a defect in supply or utilization of vitamin B₁ and often underweight.

Certainly no one diet is suitable for all cases of chronic rheumatoid arthritis. Since the etiology is still obscure, many different diets have been proposed for its treatment, usually without any scientific basis. Here, as in any chronic disease, a well-balanced diet should be supplied. So many patients have been on a diet deficient in the protective foods and frequently in meat, that the need for the foods containing vitamins, mineral salts and protein should be especially emphasized.

I believe it unwise, however, to simply effect a gain in weight in a patient suffering from rheumatoid arthritis by means of a high-calorie diet with the idea that the patient's resistance is thereby increased. Such a patient often cannot use the food elements offered so there is no point in offering more. This is probably the explanation for the hypochromic anemia seen so frequently. Likewise, the diabetic type of glucose tolerance curve indicates that the body cannot utilize the sugar offered it. The body in such a state may be thought of as having a chemical overload. Rest, which, after all, is the most valuable therapeutic agent in the disease, should include chemical rest as well as physical and mental rest.

Unless a patient with chronic rheumatoid arthritis is underweight due to a deficient food intake, his condition is usually improved little by simply increasing the total food intake. In my experience, most patients do best at the beginning of treatment at least, on a low-carbohydrate, high-vitamin diet, since this gives ample calories and supplies the food elements probably most indicated. After improvement is under way, the carbohydrate intake is gradually increased, although one often finds a sufficient weight increase on the original diet. Since the problem is often to get the patient to metabolize what is given, we usually give insulin for a time if the glucose tolerance curve shows a defect in sugar utilization or if the patient is without appetite.

We have used the following diet for chronic rheumatoid arthritis:

HIGH-VITAMIN, LOW-CARBOHYDRATE DIET

This diet includes abundant meat, fruits and vegetables with a minimum of sweet and starchy foods.

1. Eat a liberal portion each day of any fresh fish or meat such as beef, lamb, chicken.

2. Eat one or two eggs each day.

3. Take fresh vegetables both raw and cooked as follows:

(a) Eat two fresh raw vegetables from the following list.

These may be taken in salad form.

Cabbage	Endive	Radish
Carrot	Lettuce	Swiss chard
Celery	Onion	Tomato
Cucumber	Pepper	Water cress

(b) Eat at least two fresh-cooked vegetables from the following list.

Asparagus	Celery	Peas
Beets	Egg plant	Rhubarb
Broccoli	Kale	String beans
Brussels sprouts	Kohl rabi	Spinach
Cabbage	Mushrooms	Squash
Cauliflower	Onion	Tomato
Carrots	Parsnips	Turnips

4. Take fruit, especially fresh fruit in season, liberally each day. It is a good plan to eat fruits in place of made desserts and pastries; oranges, grapefruit, pears, pineapple, melon, berries and apples are especially good. Use just sufficient sugar to make the fruit palatable.

5. Drink two glasses of milk or buttermilk each day. Other beverages with a minimum of sweetening may be added.

6. Eat no cereal or bread except two slices of whole wheat bread daily.

7. Take butter, cream and salad dressings as desired.

8. Eat nuts as desired.

9. Add vitamins to those in foods as follows:

(a) Wheat germ for vitamin B. Take two tablespoonfuls each day.

(b) Fresh yeast for vitamin B. Take two cakes each day.

(c) Cod liver oil or substitute for vitamins A and D, such as two tablespoonfuls of cod liver oil twice a day, or 1 ABD capsule or halibut liver oil with viosterol three times a day.

10. Avoid the following:

All vegetables not on list.

All bread and bread substitutes, except the whole wheat bread allowed.

All cereals.

All desserts such as puddings, cookies, pies, cake, pastry and ice cream.

All very sweet fresh fruits and all dried fruits such as figs, dates, raisins and prunes unless taken only occasionally in small amounts.

All spaghetti, noodles, macaroni, rice, candy, honey, syrups, jellies.

All sugars except such as are necessary to make the food and drink palatable.

An adequate (1800-calorie) diet selected from this list with household measures is indicated below:

Breakfast:

Fruit	1 serving
Wheat germ	2 tablespoonfuls
Eggs	2
Toast—Whole wheat	1 slice
Butter	1 square
Cream	$\frac{1}{2}$ cup
Sugar	1 teaspoonful
Coffee or Tea	As desired

Luncheon:

Meat or meat substitute	2 ounces
Vegetable—cooked	$\frac{1}{2}$ cup
Vegetable—raw	1 cup
Mayonnaise or oil dressing	1 tablespoonful
Bread—Whole wheat	$\frac{1}{2}$ slice
Butter	1 square
Milk	1 glass
Fruit	1 serving
Sugar	1 teaspoonful

Dinner:

Meat or fresh fish	4 ounces
Vegetable—cooked	$\frac{1}{2}$ cup
Vegetable—raw	1 cup
Mayonnaise or oil dressing	1 tablespoonful
Bread—Whole wheat	$\frac{1}{2}$ slice
Butter	1 square
Milk	1 glass
Fruit	1 serving
Sugar	1 teaspoonful

Cream and Butter.—At least $\frac{1}{2}$ cup of cream and 3 squares of butter should be used daily. More salad dressing may be used if desired.

Sugar.—Do not use more than 3 teaspoonfuls daily.

After the patient has begun to improve, additions are allowed in the form of more whole wheat bread, baked potato or cereal and certain desserts such as ice cream. These are additions, however, to the basic diet outlined and not to replace any of the essential foods.

Chronic hypertrophic arthritis or primary degenerative arthritis occurs to a certain extent in every person past middle age and is an expression of wear and tear on joint tissue, but usually the pathologic changes are not extensive enough to cause symptoms. The disease may be accelerated by any condition which will age tissues, especially physical and nervous exhaustion, low metabolic rate, vascular disturbances or toxic absorption from the alimentary tract or from areas of infection. The initial quality of the joint as determined by heredity is most important. This disease is frequently associated with obesity, arterial hypertension or hypotension, arteriosclerosis and diabetes. The proved metabolic disorders of the joint, such as gout and alkaptonuric arthritis, produce anatomic changes in the joint which are similar roentgenographically to those in primary degenerative arthritis. There is much evidence to suggest that this type of arthritis is a chemical disturbance in the nutrition of the joint cartilage. It comes at a time of life when from a chemical standpoint the capacity of the body tissues to function normally is impaired. The patient is frequently overweight and this usually is secondary

to a lowered metabolism. The added weight is also an additional mechanical insult to the joint cartilage. The blood uric acid is frequently elevated and the glucose tolerance curve often indicates diminished carbohydrate utilization. Many of the patients have had a poorly balanced diet with excessive starch intake for a long time. It seems probable that the dietary imbalance is often responsible for a diminished utilization of vitamin B. While the cause of arteriosclerosis is unknown, it seems that the cholesterol metabolism is related to it, and this in turn is related to the lowered metabolic rate and the diet. Arteriosclerosis is responsible for the obliteration of the fine capillaries which are certainly partly responsible for the impaired nutrition and consequent softening of the articular cartilage. The diet in this type of arthritis is of prime importance, the indication usually being to supply a diet which puts as small a metabolic load on the patient as possible, is properly balanced and sufficiently low in calories. We have used a low-calorie diet selected from the low-carbohydrate, high-vitamin diet given above. Nuts are eliminated. Butter, cream and dressings are allowed for seasoning only. Eggs are omitted. All food is taken in small amounts. The following is a low-calorie (1000) diet selected from this list:

Breakfast:

Fruit	1 serving
Wheat germ	2 tablespoonfuls
Toast—Whole wheat	1 slice
Butter	$\frac{1}{2}$ square
Coffee or Tea	As desired

Luncheon:

Lean meat or substitute	2 ounces
Vegetable—cooked	$\frac{1}{2}$ cup
Vegetable—raw	1 cup
Bread—Whole wheat	$\frac{1}{2}$ slice
Butter	1 square
Milk—skimmed	1 glass
Fruit	1 serving

Dinner:

Lean meat or fresh fish	2 ounces
Vegetable—cooked	$\frac{1}{2}$ cup
Vegetable—raw	1 cup
Bread—Whole wheat	$\frac{1}{2}$ slice
Butter	1 square
Milk—skimmed	1 glass
Fruit	1 serving

If a patient with chronic degenerative arthritis is overweight or even if he is underweight and is having active symptoms from the disease, it is often most valuable at the beginning of treatment to keep him in bed for five days and to give orange juice or other fruit alone. The first day the patient is given only the juice of one orange and water is denied; no other food is permitted. The juice of an additional orange is given each day so that by the fifth day five oranges are given. At the end of this time, a 500-, 800-, and 1000-calorie diet from the list given is allowed as indicated. The length of time the intensive restriction of carbohydrate-rich food, if kept up, will be determined by the weight and general symptoms of the patient. It is best to continue indefinitely with a diet just sufficient to maintain the weight at the desired level, thus insuring the proper metabolic balance. If the diet is increased, an additional chemical strain is placed on the body to metabolize this food in order that it may either be stored as fat or excreted as end-products.

SUMMARY

No one diet is suitable for the treatment of patients with arthritis, although dietary measures are of great aid in the management of joint disease.

In those cases of arthritis in which the joint involvement is part of some general disease, there are no dietary indications other than those best for the systemic disease.

Gout is the only joint disease treated specifically by diet, but even here the dietary management is only part of the treatment of the disease.

In most cases of chronic rheumatoid arthritis there is a

marked physiologic disturbance. Frequently there are manifestations of nutritional deficiency disease as well as other metabolic variations from the normal. The diet should be high in protective foods which supply vitamins and mineral salts, adequate in protein and low in carbohydrate at the beginning of treatment. Later, the calories may be increased by adding to the carbohydrate content.

Chronic degenerative arthritis is a phase of the general slowing up of body chemical processes which naturally are the result of age and use and which unnaturally are the result of various extraneous factors. The dietary indication is to give the body as small a chemical or metabolic load as is required and to supply foods which give the most valuable nutritional elements.

THE TREATMENT OF EMACIATION

R. H. McDONALD

EMACIATION is a very general term which denotes insufficient nutrition of the body tissues. It may be due to three main causes: (1) insufficient caloric intake, (2) disturbances of digestion or assimilation from the gastro-intestinal tract, or (3) to increased katabolic processes within the body. Insufficient caloric intake is seen in starvation due to a lack of available food or improper diet. Such emaciation has an economic bearing because the condition is caused entirely by a lack of all or part of the required carbohydrates, fats, proteins, minerals and vitamins necessary for normal nutrition. Disturbances of digestion or assimilation are largely due to mechanical factors in the gastro-intestinal tract which prevent proper function—such factors are gastric carcinoma or gastro-colic fistula. The third main group includes all the varied disturbances which result in increased metabolism and among these conditions are tuberculosis, diabetes, the blood dyscrasias and neoplasms of all types.

It is obvious that emaciation is a symptom only and no attempt to treat the patient with this symptom should be made until a very careful diagnosis has established the etiology of the condition. Specific therapy can then be prescribed for the removal of the etiological factor if such be possible. It is equally obvious that no universal method of treating malnutrition can be advanced; rather each patient must be treated individually, although certain general principles are applicable in all cases.

The normal diet must contain sufficient energy-yielding food to supply the basal energy requirements in addition to

that required to meet the energy expenditures of activity. Energy may be derived from the oxidation of proteins, carbohydrates or fats, although under ordinary conditions, the greater amount of energy is derived from carbohydrates. Adequate protein must be included to supply the essential amino-acids and sufficient amounts of carbohydrates and fats must be included. The diet must also contain mineral salts of sufficient quantity and quality to maintain the skeletal structure, to preserve equilibrium between the fluid portions of the body and to supply specialized metabolic needs. The diet must also include those substances which largely are of unknown chemical nature but which are necessary for normal health—these are the accessory food factors or vitamins—and an adequate amount of water is essential to allow solution of electrolytes and to preserve proper tonicity of the body fluids. Finally, the diet must include sufficient bulk to supply the physical stimulus for peristalsis. As a general rule, approximately 40 calories per square meter of body surface must be taken to supply the basal requirement and to this must be added sufficient calories necessary for the extra energy required to meet activity. The satisfaction of this extra energy requirement varies greatly—the average adult male who sleeps eight hours and does office work will require approximately 2400 calories, whereas the active lumberman of equal size will require easily twice that amount to maintain his weight, and the six-day bicycle rider will require perhaps four times that amount.

Increased weight in the emaciated individual is dependent upon the ingestion and assimilation of food units in excess of that necessary for maintenance of the weight under usual activity. Excessive amounts of any of the food elements—proteins, fats or carbohydrates—are capable of increasing the weight. Usually the optimum protein intake lies between 100 and 120 Gm., larger amounts frequently disturbing the digestion. In convalescence where it is desirable to replace the lost body proteins, more concentrated protein foods—eggs, fowl, fish, beef, veal, milk and cheese—should be used. Increased

caloric intake is usually readily accomplished by increasing the amount of carbohydrates. For a healthy individual, the usual diet contains approximately 180 Gm. of carbohydrates which can be increased to 300 Gm., thus giving an additional 500 calories. Furthermore, the use of large amounts of carbohydrate has been shown to reduce the protein combustion and thus conserve the proteins of the body. Fat is the most readily available source of energy and represents the highest caloric value in the smallest bulk. The usual diet contains approximately 100 Gm. of fats and this can be increased to perhaps 250 Gm. with a consequent increased caloric intake of 1400 calories. Butter, cream and olive oil are fat-containing foods which should form part of the diet designed to increase weight.

The therapy of emaciation resulting from the increased metabolic processes accompanying the febrile illnesses is usually simple. In the febrile illnesses of short duration, such as pneumonia, the loss of weight is usually slight and no special attempt should be made during the course of the illness to increase the caloric intake, since the toxic gastro-intestinal tract does not tolerate or assimilate food well. During convalescence, increased caloric intake in the form of milk and cream mixtures, egg-nogs and flavored milk dishes is usually sufficient to restore the weight to normal. In the febrile illnesses of longer duration such as typhoid fever, where severe malnutrition may occur, the body tissues should be nourished throughout the course of the illness by the use of a diet high in calories. It has been demonstrated that the danger of perforation is not increased by such measures and the patient emerges in convalescence in a better condition. It is frequently advisable to feed patients every two or three hours during both the day and night and to arrange, if possible, for a total intake of 4000 calories in every twenty-four-hour period to combat the increased metabolism of the body resulting from the high, prolonged fever. Meat may tend to increase intestinal putrefaction, but sufficient protein in the form of eggs and milk must be taken to counterbalance this lack. A theoretical consideration has been advanced that fats

are less well oxidized in the patient with typhoid fever and that the intermediary products formed may increase the tendency to acidosis. Practically always, cream and butter are well tolerated. Carbohydrates may be given in large amounts preferably without cellulose content.

In the presence of any prolonged fever as pulmonary tuberculosis, it is generally agreed that the protein content of the diet should be slightly in excess of the ordinary bodily requirements. It has been shown that the traditional use of large amounts of milk and eggs has no special beneficial action and these foods should be used strictly in proportion to their food values. Fats are especially useful in these diseases, since it has been shown that it is desirable to keep the weight somewhat above the average considered to be normal.

In local diseases of the stomach such as carcinoma or gastric ulcer, where physiological rest for the organ is desirable, the use of transgastric or duodenal feeding will frequently enable the patient to retain weight and remain a great deal more comfortable. The duodenal tube may be left in place for twelve or fifteen days at a time and through it, the patient should receive feedings every two hours, care being taken that the food is administered slowly. All food should be strained and given at body temperature and this should be followed by a little water to prevent blocking of the tube. Milk, eggs, gruels, cereals, cream and normal saline solution may be given in this way and thus a high caloric intake may be insured.

In conditions which preclude feeding by mouth, certain artificial methods of feeding have been used, the oldest of which undoubtedly is rectal feeding. Unquestionably, the use of this method has been of some benefit, but in the majority of cases it has not proved to be a practical method of increasing the caloric intake. It is well known that water and salts may be absorbed from the colon and perhaps a certain amount of carbohydrates. Absorption of protein is very questionable and apparently fats are not absorbed at all. Attempts have been made to provide predigested protein products and monosaccharids, but the discomfort and inefficacy of the method

has led most clinicians to discard it. Subcutaneous feeding of proteins and fats has not proved to be practical, but solutions of glucose not stronger than 6 per cent have been absorbed very satisfactorily. The intravenous use of glucose in concentrations of 5 to 50 per cent in normal saline solution or distilled water has become an essential procedure in hospital practice for supplying extra calories, especially as a temporary method during severe disturbances of the gastro-intestinal tract. It should be administered slowly in order to avoid blood sugar levels which will allow a considerable portion of the glucose to spill over into the urine.

Metabolism may be affected greatly by thyroid hypersecretion and extreme emaciation is characteristic of the severe grades of hyperthyroidism when, despite a ravenous appetite, the markedly increased metabolism induced by the excessive thyroxin produces malnutrition. Increase in the caloric intake is impracticable. In such instances, surgical intervention in the form of subtotal thyroidectomy, although admittedly a gross form of therapy, has proven in clinical practice to reduce the excessive secretion with restoration of the normal balance. Postoperatively, the thyroid patient requires only a normal diet with some added caloric value to regain his normal weight. Failure to gain weight suggests insufficient removal of the gland or the presence of accessory thyroid tissue. In this connection, an interesting group of patients are those with malignant thyroids associated with hyperthyroidism in whom local resection gives temporary improvement with the development later of recurrent signs due to the production of thyroxin in distant metastases. Characteristically, insufficient thyroxin production, whether due to resection of too much of the gland or to idiopathic causes, is accompanied by excess weight, but in this regard, it must be remembered that some individuals who are underweight have a low metabolic rate. Such individuals tolerate thyroid extract well and may gain weight following the judicious administration of the extract. This apparently is due to the increased appetite produced by this medication.

The emaciation seen in Addison's disease is a result of gastro-intestinal disturbance and may be relieved by the use of the adrenal-cortical extract, although this constitutes replacement therapy and obviously does not cure the condition. Very severe grades of emaciation are seen in certain disturbances of the pituitary gland, the so-called "Simmond's disease," and therapy at present is unsatisfactory, but the use of newer pituitary hormones offers possibilities. The malnutrition characteristic of the poorly treated diabetic depends largely upon the constant loss of sugar through the urine coupled with the result of disturbed gastro-intestinal function. The proper use of insulin in addition to an adequate diet now permits a normal degree of nutrition for the diabetic, and such replacement therapy can apparently be continued for years, so that the diabetic now may experience his normal life expectancy. Under such management, the severe degrees of emaciation which commonly followed the starvation treatment used formerly have disappeared. It is well to remember, however, that the patient with diabetes should not be allowed to become overweight, and a degree of nutrition slightly under the normal for height and age tends to reduce the metabolic load and lessen the pancreatic strain.

The use of insulin in the treatment of malnutrition in non-diabetic patients received attention within a year of the discovery of the islet hormone, and investigators have arrived at widely divergent conclusions in regard to the value of this procedure. The usual method has been to give insulin in dosages of from 3 to 5 units, thirty minutes before meals, and gradually to increase the dosage until mild symptoms of hypoglycemia result. In most cases, an increased caloric intake has also been prescribed. The mechanism of the production of increased weight following insulin therapy is theoretical. Increased caloric intake or better assimilation of food undoubtedly are factors, the former in some cases being influenced by the fear of hypoglycemic reactions. Psychic stimulation of the appetite cannot be measured but must certainly be a factor in the sensitive individual. There appears

to be no consistent relationship between the blood sugar level and the appetite, although marked decreases in the blood sugar level undoubtedly cause a subjective sensation of hunger. It has been shown that the injection of from 10 to 20 units of insulin causes hunger contractions and an increase in gastric tonus in normal fasting subjects, and it may be that this insulin effect on the gastric muscle has much to do with the increased food ingestion which has been reported. It has also been reported that the injection of insulin increases gastric, biliary and pancreatic secretion, which would suggest improved digestion and assimilation of food as a basis for increased weight in undernourished patients. However, a true increase in weight can be attained only by increased caloric intake. In patients in whom increased appetite results from the use of insulin, benefit has been obtained. Such results are not universal and the method offers no specific remedy in the treatment of undernutrition.

SUMMARY

Severe degrees of undernutrition should be prevented by early recognition and relief of the etiologic factors. The treatment depends upon the ingestion and assimilation of an adequate diet of sufficient caloric value to provide energy not only for the basal metabolic needs and to cover whatever activity is carried on, but also to allow for some excess to produce a gain in weight. Each patient constitutes an individual problem and the diet must be adjusted according to the conditions present. Detailed diets may be found in the many excellent books on nutrition and dietetics. In cases where there is disturbance of gastric function, rectal feeding becomes of some value and intravenous feeding may be successfully carried on for short periods of time.

EMERGENCY MANAGEMENT IN THE CRISES OF HEART DISEASE

A. CARLTON ERNSTENE

SITUATIONS in which the prompt institution of proper treatment may be directly responsible for the saving of life probably are encountered more frequently in patients with organic heart disease than in any other group of individuals. A thorough understanding of the therapeutic measures available for use in patients critically ill with heart disease therefore is of considerable importance. Fortunately, practically all of the measures of established value are of such simple nature that one can easily be prepared to use them at all times.

ADVANCED CONGESTIVE HEART FAILURE

It happens not infrequently that a patient with congestive heart failure is first seen only after his condition has become critical. Usually, under these circumstances, the patient has experienced increasingly severe symptoms for days or even weeks. Examination reveals an exhausted, apprehensive individual in extreme respiratory discomfort, with orthopnea, cyanosis, engorgement of the jugular veins, an enlarged, tender liver and extensive peripheral edema. Hydrothorax and ascites may be present, and in many patients there is repeated vomiting. The cardiac rhythm may be regular or irregular; the most common type of arrhythmia observed is auricular fibrillation with a very rapid ventricular rate and a large radial pulse deficit.

In situations of this kind, the first indication is for the administration of digitalis. Because a delay of even a few

hours in obtaining the therapeutic effect of the drug may mean a fatal outcome, intravenous administration is necessary. It is important to bear in mind in this connection that when digitalis action is urgently needed, one must not rely upon intramuscular injection, and particularly is this true in the edematous patient. There are several preparations of digitalis on the market which are put up in ampules for intravenous use. Unfortunately, these preparations differ considerably in potency among themselves and, to a somewhat lesser extent, in different lots of the same product.¹ It therefore is advisable that one become familiar with the clinical action of a single preparation and confine himself to the use of that preparation. For most of the products on the market, an initial intravenous dose of 6 cc. is suitable, and the same dose can be repeated, if necessary, after an interval of four hours. After this, it is generally advisable to complete the process of digitalization either by oral administration of the drug, if vomiting has ceased, or by intramuscular injection.

If one prefers, strophanthin may be given intravenously in place of one of the digitalis preparations. This drug, however, possesses no definite advantages over digitalis and is dangerous when given in large doses. When used, the initial dose should be not more than 0.5 mg. Additional doses of 0.1 mg. may be given if necessary at intervals of four hours until a total of not more than 1 mg. has been administered. It is, of course, important to ascertain that patients to whom digitalis or strophanthin is given intravenously have not received digitalis within the preceding two weeks.

The intravenous administration of digitalis or strophanthin may produce remarkably prompt improvement in the patient who is critically ill with congestive heart failure, and particularly is this true when auricular fibrillation is present. In patients with auricular fibrillation, slowing of the ventricular rate usually is noted within five minutes after administration of the drug, and within one half hour there may be complete cessation of vomiting and great diminution in the degree of dyspnea. Strophanthin attains its maximum effect in approxi-

mately one hour and the digitalis preparations in about two hours after intravenous injection.

In addition to receiving digitalis or strophanthin intravenously, patients who are desperately ill with congestive heart failure should be given morphine sulphate immediately by hypodermic injection. The drug depresses the respiratory and vasomotor centers in the medulla as well as the higher cerebral centers, and by so doing, relieves the patient's dyspnea and his anxiety and apprehension. Not only should morphine be administered when the patient is first seen, but a second injection, usually of $\frac{1}{4}$ grain, should be given the same evening to insure a comfortable night's rest. Several hours' sleep frequently results in striking improvement in the general condition and morale of the patient.

Advanced congestive failure often is attended by the accumulation of large amounts of fluid in the serous cavities of the body. Extensive hydrothorax may be present on one or both sides and, by compressing the lung, may be responsible for a considerable part of the patient's reduction in vital capacity and resultant dyspnea. It therefore is important that the fluid be removed as completely as possible soon after the initial administration of digitalis and morphine. Less frequently, ascites is present in sufficient amounts to interfere with the movements of the diaphragm and thus contribute to the degree of dyspnea. Under such circumstances, abdominal paracentesis is indicated.

In patients with myocardial failure, the peripheral venous pressure is increased roughly in proportion to the degree of decompensation. In the presence of severe failure, the jugular veins may be engorged to the angle of the jaw even with the patient well propped up in bed. Venesection with the removal of from 250 to 500 cc. of blood may result in prompt improvement in cases of this kind and should be employed whenever the institution of digitalis therapy and other measures discussed above fail to produce satisfactory improvement. This procedure directly reduces venous congestion and diminishes the degree of dilatation of the heart. It is desirable to make

measurements of the venous pressure during the removal of the blood and to continue the bleeding until the pressure has been reduced to within the upper limits of normal. For practical purposes, however, a reliable guide is furnished by observations on the jugular veins, venesection being continued until jugular distention has been relieved. In favorable cases, the venous pressure remains low after having been reduced by venesection, whereas in unfavorable cases a more or less prompt return of peripheral venous congestion occurs.

ACUTE CORONARY ARTERY OCCLUSION

The clinical picture of sudden occlusion of a branch of the coronary arteries is too well known to require further detailed description. The condition constitutes one of the most important crises of heart disease, and the first aim in its treatment is relief of the pain. For this purpose morphine should be given promptly and, if necessary, in repeated doses. The initial dose of the drug usually should be $\frac{1}{4}$ grain hypodermically, and subsequent injections of the same amount should be given at intervals of twenty to thirty minutes until the patient becomes comfortable. If an oxygen tent is available, the patient should be placed in it, since oxygen therapy frequently is helpful in shortening the duration of the pain and in relieving dyspnea and cyanosis. Nitroglycerin should not be administered, for it will have no effect upon the pain and, by reducing blood pressure, it may further embarrass the coronary circulation. Coronary occlusion occasionally results in the rapid development of a state of profound shock with loss of consciousness. Under such circumstances, the intramuscular administration of 0.25 to 1.0 cc. of a 1:1000 solution of epinephrine hydrochloride or of 0.5 Gm. (7.5 grains) of caffeine sodium benzoate may be a life-saving procedure. The patient should, of course, be kept warm, and all unnecessary movement should be avoided. At a later period, measures may be necessary for support of the circulation or for the control of auricular fibrillation or ventricular paroxysmal tachycardia.

CARDIAC ASTHMA AND ACUTE PULMONARY EDEMA

Cardiac asthma is a form of paroxysmal dyspnea which occurs in patients with serious organic heart disease. Occasionally, its onset gives the first warning of the presence of a damaged heart, although more often the patient has experienced dyspnea or anginal pain on effort for some time before the first seizure. The attacks develop rapidly and are characterized by asthmatic breathing with both inspiratory and expiratory difficulty, orthopnea and a sense of suffocation. The paroxysm may last from several minutes to a few hours and may progress to acute pulmonary edema with frothy, blood-tinged sputum. Death may occur during the attack.

In the great majority of cases, cardiac asthma is due to failure of the left ventricle, which has been damaged previously as the result of hypertension, coronary artery sclerosis or aortic valve disease. The seizures in these cases usually occur at night, although occasionally they are induced by exertion. In a much smaller group of patients the attacks result from the presence of advanced mitral stenosis without myocardial failure. A series of such cases has been studied by McGinn and White,² who point out that, in contrast to attacks resulting from failure of the left ventricle, cardiac asthma in patients with uncomplicated mitral stenosis usually is precipitated by exertion, emotional upsets or paroxysmal tachycardia. When the heart rate is accelerated by any of these factors, the hypertrophied right ventricle expels blood into the pulmonary circulation more rapidly than it can pass through the narrowed mitral orifice. Acute pulmonary congestion develops and results in a paroxysm of cardiac asthma.

The two most effective measures in the treatment of attacks of cardiac asthma are morphine and the upright position. Morphine should be administered hypodermically as early in the attack as possible, usually in doses of $\frac{1}{4}$ grain, and should be repeated if the patient does not appear improved within fifteen or twenty minutes. Cardiac asthma is attended characteristically by orthopnea. At the onset of a paroxysm the patient is forced to assume a sitting or standing

position and frequently supports himself with his arms against a chair, table or windowsill. It is probable that the increase in vital capacity which accompanies the change from the recumbent to the erect posture contributes importantly to the relief experienced in the latter position.

Morphine and the upright position may at times fail to relieve the patient sufficiently, and other measures must then be employed. In the absence of anemia, venesection should be carried out with the removal of from 250 to 500 cc. of blood. This may result in prompt and lasting relief, particularly in patients who present engorgement of the peripheral veins. Weiss and Robb³ have observed that an effect similar to that of venesection, and often more prompt and lasting, may be obtained by applying blood pressure cuffs to the four extremities and inflating them to a pressure just above diastolic blood pressure.

In patients in whom cardiac asthma progresses to acute pulmonary edema in spite of these measures, digitalis or strophanthin should be administered intravenously in the dosages previously outlined. It is, of course, essential to ascertain that these patients have not received digitalis earlier.

PERICARDIAL EFFUSION

In the majority of cases of pericardial effusion, the amount of fluid present is not sufficiently large to embarrass the circulation importantly, and pericardial paracentesis is not necessary. Occasionally, however, an effusion becomes so extensive that the superior and inferior venae cavae are compressed and the return flow of blood into the right auricle is interfered with. Unless this excessive intrapericardial pressure is relieved, the condition may prove rapidly fatal. The most important indications that a pericardial effusion is attaining dangerous proportions consist of severe orthopnea, cyanosis, greatly elevated venous pressure and a rapid fall in arterial blood pressure with a small pulse pressure. The development of these symptoms and signs calls for paracentesis with the removal of as much fluid as is possible without producing pain,

cough or faintness. The procedure is carried out under novocain anesthesia, and the needle usually is introduced either in the left fifth intercostal space just within the outer border of dulness or in the right fourth intercostal space just inside the right border of dulness.

VENTRICULAR PAROXYSMAL TACHYCARDIA

Ventricular paroxysmal tachycardia is a relatively rare condition which is almost always due to the presence of serious organic heart disease. It occurs most commonly as a complication of coronary thrombosis and may be the forerunner of ventricular fibrillation. The paroxysm frequently is attended by serious collapse and occasionally by the rapid development of acute pulmonary edema. Levine⁴ has pointed out that it is possible to recognize this type of tachycardia by clinical means alone in a large proportion of the cases. Carotid sinus or ocular pressure has no effect upon the heart rate in this condition in contrast to the effect of these procedures in auricular paroxysmal tachycardia and auricular flutter. Furthermore, if one listens carefully to the heart, an occasional slight irregularity in rhythm will be noted, and in addition the intensity of the first heart sound will vary from time to time. The one drug of established value in the treatment of this type of tachycardia is quinidine sulphate administered by mouth. Usually, an initial dose of 3 grains is given, and this is followed at intervals of two hours by additional doses of 6 grains each until a total of not more than 6 doses has been administered. Morphine may be necessary for the relief of dyspnea, while the occurrence of acute pulmonary edema calls for the administration of oxygen.

ADAMS-STOKES SYNDROME

Ventricular standstill resulting from high-grade heart block and causing faintness, syncope and convulsions is a rare condition. Usually the seizures are of such short duration that treatment is directed toward prevention of their recurrence rather than toward relief of the actual attack. For this pur-

pose, the two most useful drugs are epinephrine hydrochloride administered subcutaneously or intramuscularly every few hours in doses of 0.25 to 1.0 cc. of the 1: 1000 solution, and ephedrine sulphate by mouth in doses of $\frac{3}{8}$ grain three or four times a day. Very rarely indeed, one may actually witness a prolonged period of ventricular standstill accompanied by unconsciousness and convulsions. The intracardiac injection of epinephrine hydrochloride (0.25 to 1.0 cc. of 1: 1000 solution) is indicated under such circumstances and may be a life-saving procedure.

CONCLUSION

The conditions which have been discussed comprise the most important of the emergencies of heart disease for which effective therapy is available. The diagnosis of these conditions is for the most part simple and certain; and if one is prepared to carry out the recommended therapeutic measures, he will not infrequently witness the recovery of a patient who at first sight seems hopelessly ill.

DIAGNOSIS AND TREATMENT OF ESSENTIAL HYPERTENSION

R. H. McDONALD

NORMAL blood pressure depends upon the two chief factors of the energy of the contracting ventricle and the resistance offered by the peripheral circulation. The former factor is operative only during the time the aortic valves are open, while the latter is present during the whole cardiac cycle. The latter depends partially upon the elastic recoil of the arterial walls and partially upon the state of contraction of the muscular elements of the vascular system. Both factors are controlled by the autonomic nervous system and are subject to variations in nervous control in response to stimulation from the cerebral cortex or reflexly from any other portion of the nervous system. The height of the blood pressure therefore, at any given moment, is dependent upon nervous control and can be varied in very short periods of time in order to maintain an efficient circulation under any condition. This flexibility of the blood pressure allows a wide range of readings in the normal individual. Under the stimulus of heavy muscular exercise or severe mental stimulation, the normal individual may have increased blood pressure readings which fall rapidly when the excessive stimulus is removed. In this connection, it is well to remember that single elevated pressure readings do not establish a diagnosis of hypertension. Even the mental stimulus of physical examination in the apprehensive individual may elevate the pressure well above the basic level. The initial readings in such persons are therefore almost invariably too high, and for this reason, the blood pressure reading should not be done until the physical examination has progressed to a point where the patient has become accustomed to his sur-

roundings, and when his confidence has been obtained. In this respect, the blood pressure reading corresponds to the estimation of the basal metabolic rate which would never be credited if it were not done under conditions which precluded, as far as possible, external stimulation. We are interested in determining the basal blood pressure, not the measure of response which occurs under stimulation, which is merely an index of the irritability of the autonomic nervous system. This latter depends upon the nervous stability of each individual and is often a constitutional factor of an inherited type. It is probably true that those individuals who have an unstable autonomic system are potential candidates for fixed hypertension, but great care must be exercised in estimating the significance of the blood pressure readings in such individuals. One patient of apprehensive type who was seen by the writer, was found on routine physical examination to have a pressure of 240 systolic, 120 diastolic when she was admitted to the hospital for herniotomy. Operation was deferred and the following day the pressure was 160 systolic, 100 diastolic. The next morning the pressure was 140 systolic, 80 diastolic. Operation was performed, and during the remainder of the hospital stay the pressure did not rise above 130 systolic, 80 diastolic. Two years later the pressure was again found to be entirely normal, although there was still considerable variability in the readings.

Minor factors concerned in the maintenance of the blood pressure are the blood volume and its viscosity. These purely physical factors are relatively stable and show variability only during severe constitutional disturbances.

In general, the hypertensive patients fall into two main classes: those in whom the hypertension is an accompaniment or sequence of a primary renal lesion, and those in whom the hypertension develops independently of any renal lesion which can be detected or, in fact, independently of any detectable organic disease. The latter group constitutes the so-called "essential" hypertension and perhaps includes a variety of conditions which have the common characteristics of arterial

hypertension rather than a single entity. It is unfortunate that a definition of essential hypertension must be set forth in terms of what it is not, but in the present state of uncertainty of the basic etiological factor, this is the only alternative. Nonrenal hypertension of known etiology is usually not included with essential hypertension. Thus, the increased blood pressure resulting from increased intracranial pressure which appears obviously to be a reflex designed to maintain an efficient cerebral circulation, is excluded as well as the paroxysmal hypertension seen in tumors of the adrenal cortex.

The early clinical diagnosis of hypertension depends upon the routine use of the sphygmomanometer with repeated readings if necessary and careful clinical evaluation of the result. Frequently, hypertension is diagnosed by this means only, in the entire absence of symptoms or signs, and thus its use is absolutely essential. The earliest clinical symptoms may be very indefinite and suggestive only of vasomotor instability so that they may be regarded as of purely functional origin. Symptoms of disturbance of the cerebral circulation, headache, dizziness, vertigo, insomnia, and inability to concentrate are frequently encountered in the individual whose work is chiefly mental, whereas in the laborer, dyspnea on exertion, palpitation, precordial distress and other evidences of cardiac embarrassment may be the initial complaints. Evidences of renal deterioration are rarely seen as initial symptoms, inasmuch as the renal degeneration is secondary to the vascular change accompanying the hypertension and this develops relatively slowly.

In many instances the presence of hypertension is only detected when a sudden circulatory disturbance impairs the function of heart or brain to such an extent that the patient is driven to seek advice. An attack of angina pectoris or a coronary thrombosis may occur in an otherwise symptom-free individual and indicate the presence of an unsuspected hypertension. Transient cerebral spasms associated with temporary paralysis, transitory aphasia or other mental upsets may call attention to the instability of cerebral circulation. Apoplexy

is frequently the initial symptom. Sudden amaurosis or other visual disturbances have been noted. Circulatory disturbances in the extremities in the form of paresthesias or even intermittent claudication are sometimes seen. Epistaxis, hemoptysis, and gastro-intestinal hemorrhage are rare complications of essential hypertension in its initial stages.

The differentiation between the renal and nonrenal types of hypertension may usually be made after a careful consideration of the history, physical examination, and certain laboratory findings. The patient with chronic hemorrhagic Bright's disease usually gives a history of an acute phase with gross urinary changes and edema or relates the onset of his difficulty to some acute infection suggestive of a streptococcal invasion. In the vast majority of essential hypertensives there is no definite starting point but an insidious development of certain symptoms which at last have culminated in a vascular accident or have been explained by routine physical examination. The elevation of blood pressure and the resultant cardiac hypertrophy is generally greater in the patients with essential hypertension and the general condition is usually much better. Anemia is much less marked in this group; urinalysis may be entirely normal at first or show only small amounts of albumin with a few scattered blood cells and casts whereas in chronic Bright's disease, there is constant urinary evidence of severe renal deterioration, which is especially evidenced by the presence of red blood cells. This difference is frequently striking when the renal reserve is measured by the *urea clearance test*.

The vascular reactions in essential hypertension have been studied extensively and evidences of increased vasomotor irritability have frequently been noted following deep inspiration, thermal stimulation, pressure on the eyeball or carotid sinus. The injection of histamine intradermally in essential hypertensives has been found to produce a much smaller "flare" than in the normal individual. Examination of the retina is of little practical importance in the differentiation of the two types of hypertension inasmuch as the vascular changes are

not in themselves characteristic in either case, but are apparently largely the result of increased pressure *per se*.

The marked frequency with which the physician is confronted with the problem of hypertension makes it a therapeutic problem quite comparable to that of malignant disease. In fact, from the purely economic point of view, it would seem that the problem is of more importance inasmuch as the great majority of severe hypertensives suffer disability in their productive years, whereas the majority of victims of malignant disease have passed their peak. It is rather interesting to note, however, that in neither the medical nor the lay mind has the problem been accorded anything approximating the study or importance accorded to malignancy.

Naturally, the purpose of any prescribed treatment would be to eradicate the cause of the disturbed circulatory dynamics since, obviously, the hypertension in itself is merely a symptom of some derangement of function. It seems fairly well established that the immediate cause of the hypertension is an increase in the peripheral resistance, a hypertonus of the vascular musculature associated with an extreme and sustained vasoconstrictor nervous impulse, the consequence of which over a period of time is vascular damage. At the present time, it appears that several causes or conditions may contribute to this state and therapy must, therefore, be devised to suit the requirements in the individual case.

Specific therapy in the present uncertain state of our knowledge is not feasible, and we must await further elucidation of the exact functional disturbance before such measures can be utilized. However, the medical profession must guard against the adoption of a too pessimistic attitude with regard to this condition. Much can be done to alleviate the symptoms and to assist in combating the various manifestations and complications of the disease. It is true that there appears to be no record of cure in any clear-cut case of essential hypertension, but on the other hand, one frequently sees patients with severe hypertension who have carried on for many years.

The prevalence of the disease and the striking nature of its

complications and sequelae have been responsible for the development of a phobia of hypertension which in itself aggravates the basal condition. The physician who has taken time to appraise his patient's lesion accurately and in so doing has established himself in his patient's confidence, may greatly help the mental peace and quietude by a frank discussion of the problem, although in general it is best to refrain from telling him the exact level of his blood pressure. Many individuals are apt to attach great importance to the exact mathematical readings and to variations of these reading at different times. The adoption of a quiet routine of life and the education of the patient to a schooled inward calm are intangible factors of the greatest importance, although admittedly, these may be difficult to attain under present economic and social conditions. Moderation in all the activities of life should be emphasized, in physical exertion in the individual of strenuous type and in mental effort in those who are accustomed to overdo in this respect. Moderation in regard to eating is essential and in the plethoric type of individual, the reduction of excessive weight will frequently be accompanied by a gratifying reduction in the blood pressure. Adequate and frequent rest and careful avoidance of an exhaustion state will often reduce the pressure below the dangerous limits, and the value of regular vacations should be stressed. Excessive heat and humidity have been shown to increase pressure and are generally poorly tolerated by patients with hypertension. Moderate exercise may be tolerated well, but the functional state of the heart should be considered.

A great deal has been written on the dietary management of increased blood pressure, but it still remains to be proved that any special diet exerts a specifically beneficial effect. Caloric restriction in the obese patient has proved of value, but the diet should be varied and it should be adequate to prevent deficiencies which are becoming more and more obvious in many of the patients who adhere to dietary fads. Especially has it been proved that the older idea of protein restriction is untenable and in itself the basis for secondary symptoms

of general weakness and anemia. A moderate intake of protein sufficient at least to maintain the nitrogen equilibrium is essential. The type of protein food is of less importance than its adequacy, and the old popular idea of the necessity of barring the red meats has no justification. Renal insufficiency in cases of arteriosclerotic renal disease, as evidenced by increased nonprotein blood values of renal origin, necessitates a lowered protein intake. Restriction of fluid intake seems justifiable only in instances of myocardial weakness and failure, but there seems no reason for forcing the ingestion of very large amounts of fluid on the theory of flushing out hypothetical toxins. Moderate restriction of sodium chloride is usually advised, but enough is allowed to make the food palatable. The use of condiments and highly spiced foods should be prohibited. It is generally agreed that the use of tea and coffee should be restricted and that the use of alcohol and tobacco should be reduced to moderate levels in those patients who feel that their absolute prohibition constitutes a hardship.

The multiplicity of drugs suggested and used in the treatment of hypertension is eloquent evidence of the regrettable fact that all fall short of anything approaching a specific effect. Probably, the drug therapy most used is some form of nitrite such as amyl nitrite by inhalation which is the quickest in action although most evanescent in effect, $\frac{1}{100}$ grain of nitroglycerin, which is less rapidly active but more sustained in effect, 1 or 2 grains of sodium nitrite which is still slower in action but has a more prolonged effect. From $\frac{1}{2}$ to 1 grain of erythrol tetranitrate is again slower in action but with still more prolonged effect. Its action depends upon the formation of nitrite within the body, the nitrite in this case as in each of the above substances, acting by a peripheral vasodilation, the effect being either directly upon the smooth muscle of the arterioles or upon the sympathetic myoneural junction. More recently, an attempt has been made to prolong the effect of vasodilation by the use of bismuth subnitrate in capsules of 10 grains each which are given by mouth. The slow decomposition of the nitrate to nitrite by the action of intestinal

bacteria theoretically provides a prolonged source of medication. It has never been established that the use of the nitrites offers any more than temporary symptomatic relief, but these undoubtedly increase the comfort of certain patients and are especially valuable in combating symptoms secondary to periodic elevations of pressure, notably anginal attacks and the transient cerebral phenomena associated with cerebral vascular spasm. It is frequently observed, however, that the sudden reduction of hypertension by the nitrites results in discomfort and evidences of insufficient cerebral circulation, especially in arteriosclerotic patients.

Iodides in minute concentration have been regarded as vasodilators, but clinically they appear to be useful only in certain cases because of their alterative action. Calcium salts have been recommended on theoretical grounds but clinically are of little value. Sulphocyanates and thiocyanates have been widely used and in a few cases seem to cause subjective improvement and are effectual in some reduction of pressure. However, toxic symptoms such as exfoliative dermatitis or symptoms referable to the cerebral cortex have militated against their more widespread use. I have found the purine derivatives, theobromine and theophylline in various forms, to be useful in securing considerable subjective relief, although it appears certain that no consistent manometric success may be expected from their use. Mild sedatives, either alone or in combination with some of the above therapeutic agents, have certainly helped greatly in the treatment of patients with these difficult problems. Especially is this true in the patient who displays marked sympathetic hypersensitivity. Bromides and barbituric acid derivatives appear most suitable for prolonged administration, but for emergency use, codeine and various forms of opium may be necessary.

The literature contains numerous articles which record some degree of success with many other preparations. The use of liver extract failed to justify the earlier hope that this would prove to be an effective method of treatment. Benzyl benzoate has been used and more recently an extract of watermelon seed has been accorded some therapeutic virtue. For the most

part, organotherapy has been disappointing, but the use of ovarian hormone has been distinctly useful in those cases of hypertension associated with the menopause. The use of the high-frequency current and diathermy has found support by some observers, but the effect is limited. Vigorous physiotherapy, massage and warm baths should be used with care.

The failure of the physician to produce a cure has drawn the surgeon into the problem and in recent years, a considerable literature has accumulated on the subject of operative intervention. In general, the theory underlying the surgical attack is the relief of vasoconstriction by cutting the sympathetic nerves which supply the splanchnic area, thus preventing constriction of a considerable fraction of the vascular bed and providing a sort of safety valve. It is also argued that such a procedure prevents renal vasoconstriction and good experimental evidence has been presented that narrowing of the renal vascular supply will cause a general increase in blood pressure. Further, it is argued that such a measure will decrease adrenalin production. However, it has never been proved that ordinary hypertension is due in any way to increased adrenalin production although there are well proved instances of paroxysmal hypertension associated with adrenal tumors. Denervation of the adrenal glands has been performed either alone or with splanchnic section in the hope of reducing the sympathetic vasoconstrictor impulse. Some favorable results have been reported from these surgical procedures, but success has been only partial in the majority of cases and lacking in others.

The whole question of the etiology of essential hypertension requires further elucidation before a more logical therapy can be expected. It constitutes a problem of tremendous economic importance and merits the careful study and consideration of the medical profession in order that the resultant disability and discomfort may be relieved. In the meantime, the careful clinician must continue to study these patients individually, and use every method at his disposal for their comfort and relief.

REMARKS ON A FEW COMMON SKIN ERUPTIONS SEEN FREQUENTLY DURING THE SUMMER MONTHS

E. W. NETHERTON

IN discussing the increased seasonal incidence of certain common dermatoses, we are in reality referring to the degree of exposure of the population to environmental hazards during certain months of the year. The degree of exposure to common hazards will naturally be influenced by the climate, geographical location, occupation, clothing, and the types of recreation of an individual. In the semitropical climates of some of the southern states, the inhabitants are not subjected to the seasonal changes in temperature which necessitate a modification of clothing or which result in changes in recreational activities such as are the people who live in the northern or temperate climates. Therefore, the incidence of common dermatoses in the South should not vary a great deal. However, in the temperate climates with the advent of the summer months, people of the cities emerge from a relatively sedentary life to engage in their favorite outdoor recreation such as golf, swimming, picnicking, fishing, etc., while those in the rural communities become actively engaged in outdoor occupations such as farming and gardening. At this time of the year, an individual wears less clothing and perspires freely; a larger portion of his body is exposed to intense sunshine; he is frequently bitten by insects and frequently comes in contact with many types of vegetation. Therefore dermatitis venenata, fungal infections, insect bites with secondary infection and cutaneous eruptions resulting from increased perspiration and the deleterious effect of excessive heat and ultraviolet rays are especially common at this time of the year.

Some of the common dermatoses whose incidence is influenced by the factors just mentioned are:

1. Those resulting from exposure to intense sunshine.
 - (a) Erythema or dermatitis solare (sunburn).
 - (b) Lentilles or freckles.
2. Those resulting from intense heat and increased perspiration.
 - (a) Miliaria crystallina. Heat rash or prickly heat.
 - (b) Intertrigo.
3. Insect bites—browntail moth dermatitis.
4. Dermatitis venenata resulting from contact with plants or their pollens, bathing suit dermatitis, etc.
5. Parasitic infections.

The deleterious effect of sunlight on the skin is produced by the actinic or ultraviolet rays, rather than by the heat rays. This is the same biologic reaction which is produced by modern actinotherapy. Individuals with delicate skins and fair complexions are especially susceptible to the injurious effects of the actinic ray. The objective signs appear a few hours after exposure. The face, neck, upper portions of the trunk or the parts of the body most frequently exposed are the areas of predilection. There is first a sensation of smarting and itching followed in a short time by erythema and edema. In cases of severe and extensive sunburn, there is marked edema with vesicular and bullous lesions and associated constitutional symptoms such as general malaise, temporarily impaired kidney function and edema of the lower extremities. As the acute cutaneous reaction subsides, desquamation occurs and a variable degree of pigmentation results which tends to protect the individual from subsequent exposure to the actinic rays. Superficial scarring sometimes occurs in severe cases.

In some individuals small pigmented macules or freckles are particularly prone to develop on the face and dorsum of the hands when they are exposed to sunlight. Macleod¹ states that these individuals do not readily become sunburned. Ordinarily, the freckles decrease in number during the winter months; however, in localities where the winter days are clear

and the snow plentiful, both sunburn or dermatitis solare and freckles may result from the reflection of the actinic rays by the snow.

Although this discussion is concerned mainly with common conditions, three other dermatoses should be mentioned: these are xeroderma pigmentosum, hydroa vacciniforme, and lupus erythematosus. These conditions are sometimes referred to as light sensitive dermatoses. The exact mechanism of their causation is unknown; however, it is known that the actinic ray of sunshine will precipitate an attack of hydroa or aggravate a xeroderma pigmentosum. In the past many observers have felt that probably some photosensitive substance in the blood, such as the porphyrins, was an important factor in the causation of these dermatoses. More recent reports do not verify this opinion. Templeton and Lunsford² were able to produce porphyrinuria in patients not sensitive to light by exposure to ultraviolet light and have observed porphyrinuria in patients suffering from dermatoses which were not due to light sensitization. Likewise, porphyrinuria is present in only a small percentage of the patients with light sensitive dermatoses. In an excellent article, Anderson and Ayres³ have recently reviewed the literature and discussed the problem of light sensitive dermatoses. They submit evidence which they believe points to a disturbed sulphur metabolism as a factor in the production of light sensitization.

Xeroderma pigmentosum is a rare disease with a familial tendency. It appears early in life, starting as freckle-like pigmentation with white atrophic areas and telangiectasia. As the disease progresses, warty growths, ulceration and finally carcinoma develop, and death occurs usually before the patient reaches adult life.

Hydroa vacciniforme is also a rare condition. It is characterized by a recurrent papular, or papulovesicular eruption occurring on the face, neck, back, hands and forearms. In severe cases, bullae and superficial ulcers occur. After repeated attacks which occur during the summer months, scarring results.

Lupus erythematosus which is characterized by well-defined, persistent erythematous, scaly plaques, which show enlarged plugged follicles and subsequent central atrophic scarring, occasionally makes its initial appearance following a sunburn. It may be considered as one of the sequelae of sunburn. Because of this, it is unwise and unsafe to treat this condition with actinotherapy.

The treatment of sunburn or dermatitis solare is symptomatic. In the acute erythematous stage without vesiculation, a cool evaporating and protective lotion or powder should be used. Creams and ointments are not satisfactory and add to the discomfort of the patient because they prevent radiation of the heat from the acutely inflamed tissues. The well-known calamine lotion with 1 per cent phenol is a very satisfactory preparation or the following powder is useful:

R _x	Gm. vel cc.
Thymol.....	7
Pulv. boric acid.....	60
Pulv. starch.....	30
Talcum.....	q. s. ad 120
M. and ft. pulv.	

If vesiculation has occurred, the vesicles should be drained using aseptic precautions and a moist dressing of Burrow's solution, 1 part to 12 or 15 parts of water should be applied. In severe cases, the patient should be confined to bed. After the acute stage has subsided and desquamation has started, a bland ointment such as the following is indicated:

R _x	Gm. vel cc.
Phenol.....	3
Zinc oxide.....	8
Pulv. starch.....	8
Cold cream.....	10
Vaseline.....	q. s. ad 30
M. and ft. ung.	

Various commercial preparations are offered to the public for the prevention of sunburn, but many are of doubtful

value. Various drugs which have been considered to absorb the ultraviolet rays have been incorporated in creams and applied to prevent sunburn. Quinine is one of the most commonly used drugs. Salsberg⁴ has found the following preparation very satisfactory for the prevention of sunburn:

R	Gm. vel cc.
Quinine hydrochloride.	18
Zinc oxide.	6
Glycerine.	12
Rose water.	120
M. and ft. lot.	

Sharlit⁵ recommends phenyl salicylate (salol) in 10 per cent strength incorporated in cold cream. This cream is applied in a thin layer.

Miliaria crystalline commonly called heat rash or prickly heat is due to excessive heat; consequently it is most prevalent during hot weather. It is seen particularly in infants who are clothed too warmly. Heavy woolen underwear, overeating, and violent exercise with profuse perspiration contribute to its causation. Obese individuals or those whose occupation necessitates their exposure to high temperatures such as bakers and cooks are especially prone to have miliaria. This eruption is not a serious one but in severe cases, the itching and burning sensations are especially troublesome in the early stage of the eruption. The eruption is characterized by very small, pointed or conical papules many of which develop a small vesicle at the apices. There are also small vesicles on erythematous bases scattered throughout the eruption. The lesions occur in clusters, are very numerous and remain discrete. The papules are seldom larger than a large pinhead. In order to observe the characteristics of the individual lesions, the eruption must be examined by a magnifying lens. The onset of the eruption is preceded by profuse perspiration and is accompanied by itching and burning of varying severity. The wrist line, thighs, upper portion of the trunk, and neck are the areas most frequently involved. Severe cases may become

complicated by impetigo, pyodermia or eczematization as a result of scratching.

The management of miliaria is not a complicated problem provided the patient can avoid exposure to excessive heat and perspiration. The underclothing should be light, preferably of cotton; the diet should not exceed the needs of the patient; and the body should be kept clean by a daily bath. In severe cases the bath should be of an alkaline type. This is prepared by adding 4 ounces of sodium bicarbonate and a paste made with water and $\frac{1}{2}$ pound of corn starch to a bath tub of average size half full of lukewarm water. Instead of this soda and starch mixture, 20 grains of potassium permanganate may be added to the bath. Following the bath the following lotion will usually be beneficial,

R _x	Gm. vel cc.
Phenol.	1 2
Prep. calamine.	8
Zinc oxide.	8
Glycerine.	3
Rose water.	q. s. ad 120
M. and ft. lot.	

or a powder such as,

R _x	Gm. vel cc.
Salicylic acid.	2 4
Pulv. boric acid.	40
Pulv. zinc oxide.	40
Talcum.	q. s. ad 120
M. and ft. pulv.	

If there is a secondary pyoderma or a tendency to the development of furuncles which are more frequently seen in infants, potassium permanganate should be used in the form of baths or in the form of moist packs in 1:10,000 solution followed by an application of a 2 to 5 per cent ammoniated mercury ointment. The anointed surface should then be dusted with borated talcum.

Intertrigo is a term used to designate the erythema or der-

matitis which results from the friction of two opposing cutaneous surfaces. It occurs most commonly on the inner surface of the thighs, in the gluteal fold, in folds of the abdomen or under pendulous breasts. The friction and excessive sweating of contiguous surfaces are the most important exciting factors. Uncleanliness as well as too frequent use of irritating soaps for bathing contribute to the causation of intertrigo. As would be expected, the condition is more prevalent in obese individuals. Intertrigo of the thighs is occasionally associated with diabetic vulvitis.

In adults, intertrigo involving the inner surfaces of the thighs must not be confused with an epidermophyton infection. In intertrigo the eruption is definitely symmetrical, it is not sharply marginate and the borders are not obicular as in the case of epidermophyton infection. In doubtful cases, a search should be made for fungi in the scales taken from the lesions.

A condition which some of the earlier authorities classified as a type of intertrigo involves the gluteal folds and adjacent surfaces of the buttocks of infants; this is sometimes called Jacquet's dermatitis which must be differentiated from congenital syphilis. The lesions of congenital syphilis are of a darker color, are slightly infiltrated and are associated with other signs of congenital syphilis. If moist lesions are present, a dark-field examination should be made for the spirochete especially in cases where the diagnosis is doubtful.

Cleanliness with a minimum of irritation or trauma of the affected surfaces is of prime importance in the treatment of intertrigo. Ointments tend to increase the maceration of the epidermis, consequently lotions and dusting powders are most acceptable. The powder and lotion advised in miliaria will be especially valuable in intertrigo. Occasionally, the skin may become lichenified after the more acute phase of intertrigo has subsided. In such cases the use of a mildly stimulating and antipruritic ointment is indicated. The following is recommended:

R	Gm. vel cc.
Ung. picis lig.....	4
Salicylic acid.....	1
Pulv. zinc oxide.....	4
Pulv. starch.....	8
Ung. diachylon.....	4
Vas. alb.....	q. s. ad 30
M. and ft. ung.	

Cooke⁶ has demonstrated that the bacterial production of ammonia is the important etiological factor in the production of the dermatitis of the gluteal fold in infants which is often considered as an intertrigo. He found that if the diapers, after wearing, were rinsed in a 1:4000 solution of mercuric chloride and allowed to dry, the production of ammonia ceased. In severe cases, he recommended the application of Lassar's paste with 4 per cent balsam of Peru; however, in the average case the treatment of the diapers was sufficient.

There are many kinds of insects which frequently bite human beings especially during the summer months. Those insects which are apt to be especially annoying are: (1) the common flea or *Pulex irritans*, (2) chicken louse (*Dermanyssus avium*), (3) mosquito (*Culex anxifer*), (4) gnat (*Culex pipiens*), (5) various types of flies of which the black fly of the genus *Simulium* causes the most intense local reaction, (6) bee, wasps and ants, (7) Harvest bug or *leptus*, (8) chigger (*Pulex penetrans*). There are other insects which may prove troublesome to man in various localities but this incomplete list includes the most common insects which are encountered in the temperate climate during the summer months.

The cutaneous manifestations of most of the various insect bites have one characteristic in common—namely the early lesion is urticarial. The intensity of the local reaction varies with the type of insect, but more particularly with the susceptibility of the individual who is bitten.

The lesions may be few or numerous; they occur most frequently on the exposed portions of the body and on the lower portions of the legs, about the ankles and on the feet. The most common type of lesion is a small erythematous spot or

an urticarial papule with a central puncta. If the inflammatory reaction is marked, a vesicle will develop at the site of the puncture. In some instances, the vesicle becomes a pustule: therefore, the eruption may assume the characteristics of an urticarial, papular, papulovesicular and papulopustular dermatitis. The bites of some insects, such as the flea and the black fly, cause small hemorrhagic or purpuric spots at the site of injury. The flea often bites several times in quick succession thereby producing a row of bites. In the case of the chigger, the very small, impregnated female parasite burrows into the skin and frequently produces small cutaneous abscesses, swellings and large vesicles or pustules. A secondary impetiginous dermatitis is not uncommon when chigger bites are numerous.

As a matter of general interest, we should add to the list of common insects first mentioned—the browntail moth. Strictly speaking the eruption sometimes produced by this moth is not an insect bite. This moth, so far as I am aware, does not have a wide distribution in the United States; however, if we are familiar with the dermatitis which results from contact with this moth or its caterpillar, we may find that it has spread from the New England states and adjacent portion of Canada where it has been responsible for large numbers of cases of dermatitis. If I have seen a case of browntail moth dermatitis, I have failed to recognize the condition. G. C. White of Boston was the first to recognize and report cases of browntail moth dermatitis, and later his colleagues, Meeks, Towle, and others added to our knowledge of this condition. In 1909 Potter⁷ reviewed the literature and reported a case of generalized dermatitis which resulted from contact with this moth. Although it was known that the dermatitis resulted from the penetration into the skin of the barbed nettling hairs of the moth and its caterpillar, it remained for Tyzzer⁸ to prove that the irritation in the case of browntail moth dermatitis was due to a poisonous substance contained within the hairs.

The caterpillar reaches its full growth in June and the

moth emerges about the middle of July; consequently, this condition is seen most frequently during these months. It may occur at other seasons following contact with clothing in which the barbed hairs have lodged and may result in a dermatitis. The eruption which is usually produced by the barbed nettling hairs of the browntail moth most frequently involves the face, neck and arms. It appears as itchy erythematous macules which develop into pea-sized urticarial lesions. In severe cases, the lesions may become confluent; however, the tendency is for them to remain discrete.

The treatment of most insect bites is directed toward relieving the itching because in most instances, the local inflammatory reaction which follows the sting will subside in a day or so. In the case of the chigger, the insect should be removed from the skin. Stelwagon and Gaskill⁹ state that this may be accomplished by rubbing in fats or petrolatum. To relieve the itching, the calamine, phenol and menthol lotion previously mentioned is very satisfactory. In cases complicated by an impetiginous infection, the lesions should be cleansed well by removing all crusts and all the undermined epidermis of bullous lesions. The involved areas should then be treated with potassium permanganate solutions and the ammoniated mercury ointment suggested for the impetiginous infection which sometimes occurs in miliaria. Five per cent gentian violet in 20 per cent alcohol painted on the cleansed lesions is a dry type of treatment which may, at times, be substituted for the permanganate packs and mercury ointment.

DERMATITIS VENENATA

Dermatitis venenata in its broadest meaning refers to any dermatitis which develops in individuals after they have come in contact with various substances to which they are sensitive, usually chemicals or some type of plant. Eruptions resulting from contact with common irritants such as strong acids which are injurious to all individuals are to be distinguished from dermatitis venenata. For the present, we are not interested in the varied clinical manifestations of dermatitis venenata in

its broadest meaning. We will consider only the dermatitis caused by plants, particularly ivy dermatitis. Although the list of plants known to cause a dermatitis is constantly being increased, poison ivy or *Rhus toxicodendron* is the plant which is responsible for the largest number of cases. Ivy dermatitis is characterized as an acute erythematous, edematous, vesicular eruption. The vesicles vary in size from a pinhead to that of a split pea. In severe cases, there is considerable edema with formation of bullae. The development of vesicles along a scratch mark is a sign of diagnostic importance as it signifies that some injurious substance was deposited on the skin at the time the injury was sustained.

The areas of predilection for ivy dermatitis are the exposed surfaces of the body—the face, neck, hands and arms and in children about the knees. In many cases, the dermatitis eventually develops on other portions of the body as the irritant is spread by the hands and clothing. Males invariably develop a dermatitis on the genitalia because of contact with the hands during micturition.

A specific treatment for ivy poisoning has not been discovered. Many remedies have been proposed but none can be said to be particularly efficacious. The susceptibility of the individual, the extent of the contact as well as the care which has been exercised to prevent the dissemination of the irritant over the cutaneous surfaces not only influences the severity of the dermatitis, but also affects its duration and its apparent response to therapy. Treatment should be directed toward the removal or neutralization of the irritant, the prevention of its dissemination, and the relief of subjective symptoms. Another procedure which is of questionable value is the use of the *Rhus* antigen as a therapeutic and preventative measure.

McNair¹⁰ has shown that the irritant of *Rhus toxicodendron* is a nonvolatile resinous sap, the active principle of which is lobinol. Lobinol is soluble in ether, chloroform and alcohol, and is precipitated by lead acetate. McNair also speaks favorably of the use of potassium permanganate which was advocated by Syme¹¹ for the treatment of ivy dermatitis.

The various types of treatment which have been advocated cannot be discussed; however, the following procedures will suffice in most instances. The involved areas are first mopped with cotton saturated with a solution of equal parts of alcohol and ether. One small sponge should be used once or twice and then discarded. The vesicles and bullae are drained using aseptic precautions and their contents removed from the surface of the skin. The skin is then mopped with a 0.5 to 1 per cent aqueous solution of potassium permanganate and allowed to dry. After this, calamine lotion with 1 per cent phenol is applied. The permanganate and calamine lotion should be applied twice a day until the acute inflammation has subsided while the alcohol and ether is used but once in each area. If the dermatitis is disseminated, potassium permanganate baths are indicated. A bland ointment such as ung. zinc oxide with 3 or 4 per cent ichthyol should be used after desquamation has started.

The use of ferric chloride is undesirable because of the danger of permanent discoloration of the skin which may occur when this chemical comes in contact with cutaneous abrasions.

No doubt procedures other than the ones just mentioned are equally good, but rather than to enlarge upon the question of topical remedies, let us consider briefly the value of the Rhus antigen as a therapeutic and preventive measure. Obviously, the ideal procedure would be one which would desensitize a susceptible individual to any particular irritant and also prove equally effective therapeutically in cases in which a dermatitis had already occurred. Schamberg¹² was the first to record in the American literature the results of such an attempt in the case of ivy poisoning. He advocated the oral administration of a dilute tincture of Rhus toxicodendron. Later Strickler made several reports on the value of subcutaneous and intramuscular injections of alcoholic extracts of the ivy plant. In 1923¹³ he combined his findings with a tabulation of results of other physicians who had used this antigen in the treatment of ivy dermatitis. All these reports were very encouraging and led to an extensive use of Rhus

antigen as a therapeutic and preventive measure. The early alcoholic extracts caused considerable pain but the more recent preparations in oil vehicles are painless. The early enthusiasm for this procedure resulted from clinical impressions rather than an evaluation of facts reached after a critical immunologic study. In more recent years, the pendulum of enthusiasm has swung back and at present there is considerable doubt regarding the efficacy of this type of treatment.

Early in the development of ivy antigen for desensitization, Corson¹⁴ pointed out that the procedure was not entirely safe. He reported a case of a severe generalized dermatitis which developed soon after three injections of the Rhus antigen in a patient who was known to be sensitive to ivy. The antigen was given as a prophylactic measure.

In 1929 Templeton¹⁵ again warned of the possible untoward reactions which may result from the toxin treatment of dermatitis venenata. He observed cases in which large urticarial swellings developed at the site of the injection as well as a generalized urticaria. In his cases, extracts of poison oak were used.

Krause and Weidman¹⁶ were the first to analyze critically the various phases of this problem. They attempted to produce ivy dermatitis in animals but failed; consequently, they reported their findings which were based on experiments carried out on humans. They observed, among other things, that the dermatitis was not spread by the serum in the vesicles of ivy dermatitis, and that injection of ivy extracts did not protect susceptible individuals against a dermatitis when the irritant was applied to their skin. They doubted whether the antigen was of any therapeutic value.

Spain and Cooke¹⁷ believe that some immunity to the Rhus toxin can be obtained by a series of injections starting with small doses of large dilutions of the extract. They feel that there is a degree of clinical immunity, even though no change can be demonstrated by patch test with the active principle. Gowen¹⁸ obtained favorable therapeutic and prophylactic results with two injections of almond oil extract of Rhus toxic-

codendron. Other observers have not obtained such a good response to the use of the antigen; consequently, it occurred to Maisel¹⁰ that immunization could best be obtained by subjecting the skin of a susceptible individual to contacts with small increasing doses of the extract of poison ivy. This was tried in one case with excellent results. The method used by Maisel was a daily bath in a measured quantity of water to which had been added a measured amount of the tincture of *Rhus toxicodendron*. The initial bath consisted of 4 drops of the tincture to 10 gallons of water. The amount of tincture of *Rhus toxicodendron* was increased and the amount of water decreased until on the twenty-fifth day the bath consisted of 15 cc. of the tincture and 4 gallons of water. When 30 cc. of tincture to 4 gallons of water was used, an acute general pruritus would develop. Following this series of baths, the patch test with ivy extract was only slightly positive at the end of twenty-four hours.

Straus²⁰ was unable to produce sensitization in new-born infants either by the oral administration or by the subcutaneous injections of an alcoholic extract of poison ivy; yet in another series of experiments he was able to sensitize 72.9 per cent of 48 infants by the application of an ivy paste to the skin. These observations are both interesting and significant because they present the question that if the oral or subcutaneous injections of ivy extract cannot sensitize an individual, it is unlikely that a similar procedure will desensitize one who is susceptible to the plant. The fact that acquired sensitization to ivy is produced by contact of the epidermis with the resinous sap of the plant as well as the observation of Maisel tends to further justify this presumption.

My experience with the ivy antigen has been confined mainly to its use as a therapeutic agent. I have seen the patients after the acute dermatitis has already been established and they have failed to return later for prophylactic treatment. However, I have seen several cases in which injections of the *Rhus* antigen had failed to prevent ivy poisoning. I have observed instances of the complication mentioned by Temple-

ton¹⁵ and have failed to see a single case in which I was convinced that the use of the antigen was of distinct value as a therapeutic measure.

I realize that the question of the advisability of using Rhus antigen is still a debatable one; however, I believe that the observations previously cited create considerable doubt regarding the efficacy of this procedure. In any event, the early enthusiasm of the profession for this use of ivy antigen has waned materially.

Another type of contact dermatitis which is being more frequently recognized is that produced by plants of the ragweed family. The dermatitis may result from contact with the plant or its pollen. The irritant is contained in both the oil of the plant and in the pollen. In susceptible individuals, contact with the pollen in the dust of the air is sufficient to produce a dermatitis. There is a seasonal occurrence of ragweed dermatitis. It appears late in July or early in August and disappears after the first frost. However, if the susceptible individual is a farmer, recurrences may occur at other times of the year as a result of contact with the weed or its pollen in hay and grain. Brunsting and Anderson²¹ recently reviewed the literature and reported 18 cases of ragweed dermatitis and pointed out that since all the reported cases of ragweed dermatitis have occurred in adults, evidently sensitivity to this plant is acquired only after long contact with the irritant. The eruption consists of a diffuse redness with a variable amount of edema and a very slight amount of vesiculation as contrasted with the marked vesiculation of ivy dermatitis. The dermatitis is more of the subacute type. The exposed surfaces are the areas of predilection.

The treatment of ragweed dermatitis is symptomatically similar to that recommended for dermatitis venenata—namely, cooling, evaporating lotions or wet dressings in the acute stage and bland ointments as the inflammatory reaction subsides.

Brunsting and Anderson²¹ treated 8 cases with intramuscular injections of the specific oils of the ragweed which had been

recommended by other observers. Their results were inconclusive.

At the time of their report they were giving preseasonal treatment to a few patients but have not reported on the value of this procedure.

SUMMARY

We have briefly discussed a few of the dermatoses commonly seen during the summer months. We had hoped to discuss other dermatoses, such as impetigo and epidermophyton infection, which are seen frequently during this season of the year, but space will not permit. We should bear in mind that although the dermatoses which we have discussed are encountered most frequently during the warm weather they may also be seen during the winter months.

PRURITUS VULVAE

E. W. NETHERTON

ITCHING of the vulva is a common complaint which occurs most frequently at the menopause or during the middle decades of life. The discomfort may vary from that of a slight sensation to that of a very distressing and agonizing pruritus. Whether pruritus is generalized or localized, it is a subjective symptom and not a disease in itself.

The mechanism of the production of itching is obscure; however, its causes are many and the degree of the sensation is influenced by individual susceptibilities and the intensity of the particular stimulus or irritant. Clinical observation has demonstrated that in many instances pruritus vulvae must be considered as a symptom of some disturbance which is localized in the anogenital region or as a manifestation of some general or systemic disease, but in a large group of cases of pruritus vulvae definite causes cannot be determined. However, with a better understanding of the rôle of allergy, nutritional deficiencies, endocrine dysfunctions and psychoneurogenic factors, the frequency with which diagnoses of idiopathic pruritus are made will decrease.

Because of the multiple and varied factors which may produce this distressing condition, it is necessary that in each case a painstaking investigation be made for possible local, regional or constitutional abnormalities which may be of etiologic importance. In some instances, the cause of pruritus vulvae can easily be determined and eradicated, but in a large number of cases in which the condition is chronic, a very careful study is necessary. Although in many instances the reward for such a laborious and time-consuming task will be

disappointing, it should be recommended in all cases where the etiology is obscure; otherwise, we would be guilty of dereliction of duty by simply advising the patient to use some palliative treatment which frequently gives only temporary relief.

All the conditions which have been reported as causes of pruritus vulvae have not been included in this discussion but only the more common causes will be considered. A grouping similar to that used by Davidson¹ is satisfactory:

I. Pruritus vulvae resulting from an inflammatory process in the skin and mucous membranes of the vulva and genito-urinary tract. In cases in which there is an associated pruritus ani, pathologic changes in the rectum and about the anus must be looked for. In this group, the most common, direct and contributing factors are:

(a) Bacterial infection—*Bacillus coli*, staphylococci or streptococci.

(b) Fungous infection.

(c) Parasitic infestations.

1. *Trichomonas vaginalis*.

2. *Oxyuris vermicularis* or pinworm.

(d) Fixed drug eruption, such as phenolphthalein.

(e) Hypersensitivity to chemicals commonly used in douches or as contraceptives.

(f) Cervicitis, cystitis and proctitis.

II. Cases where itching is a symptom of some particular dermatosis in which lesions are either limited to the anogenital region or are associated with characteristic lesions on other portions of the body such as:

(a) Lichen planus.

(b) Kraurosis, or leukoplakia vulvae.

(c) Circumscribed neurodermatitis.

III. Cases in which the pruritus is a symptom of some systemic or visceral disease. The most common of these diseases are:

(a) Diabetes.

(b) Deficiency states such as achlorhydric anemia.

- (c) Food allergy.
- (d) Endocrine dysfunction.
- (e) Psychoneurosis.
- (f) Chronic diseases of the abdominal and pelvic viscera.

IV. Cases of primary pruritus in which the itching is some unexplained irritation of the nerve terminals.

In pruritus vulvae, the itching is usually paroxysmal and is more severe at night. It may be limited to the region around the clitoris or the labia or the entire vulva may be involved; occasionally, there is an associated pruritus ani. The objective findings vary greatly. In severe chronic cases, the skin of the vulva is dry, slightly scaly and leathery, showing accentuated markings on the skin surface or cross hatching, which is characteristic of lichenification. There may be excoriations, and the skin surface around the clitoris and on the small labia is frequently gray, thickened and slightly edematous. These changes are the result of trauma resulting from scratching. Maceration of the epidermis with weeping and crusting may result from secondary infection. In some cases the objective findings are negligible; however, if the itching is severe and persistent, the scratching, which is inevitable, frequently produces lichenification of the skin. Occasionally when the complaint is of long standing the itching may be present for some time after the apparent cause has been removed.

What are some of the objective findings in the various groups of pruritus vulvae which have been mentioned?

I. (a) The importance of localized bacterial infection in the production of pruritus vulvae has not been determined. A few years ago the attention of the profession was aroused by the enthusiastic reports of Murray,² Winfield,³ and Knowles and Carson⁴ in the use of *Streptococcus faecalis* and *Bacillus coli* vaccines in the treatment of pruritus ani. In some of these cases, itching of the vulva also was present. The results reported following the use of this type of vaccine therapy were exceptionally encouraging, but these authors did not conduct their bacteriological studies carefully and they failed to

present convincing evidence that these organisms, which are practically always present in the anogenital region, were the specific cause of the pruritus. Later Montague⁶ made a more careful study of this problem and although he favored the theory of bacterial infection in some cases, his observations indicated that the staphylococcus and colon bacillus were probably the infective agents. As Montague has aptly stated, the explanation of bacterial invasion as the cause of pruritus in the anogenital region is most alluring. However, there are no objective signs which may be considered as diagnostic evidence of a bacterial type of pruritus ani and vulvae.

(b) Fungous infections have a predisposition for the folds of the body where there is heat and moisture. The favorite sites for an epidermophyton infection are the feet, groins, gluteal folds and axillae. Consequently, it is not surprising that occasionally the folds of the vulva likewise become the site of this infection. In the cases of pruritus vulvae due to fungous infection, there is usually evidence of a similar infection in the groins or interdigital spaces of the feet. In all cases, the feet should be examined carefully for fissuring and maceration between the toes, vesiculation and desquamation on the plantar surfaces, and for well demarcated orbicular, brick-red, slightly scaly plaques in the groins and about the anus. The absence of lesions in these regions does not rule out the possibility of a fungal infection of the vulva. The labia and skin of the vulva should be examined carefully for erythematous raised plaques which may be small and only fairly well demarcated. If such lesions are present, repeated scrapings and cultures should be made before the possibility of a fungous infection can be ruled out. In some instances, there may be only a few small areas, while in others there are lesions in the groin, gluteal folds, and on the vulva and in cases of long standing, the skin of the vulva becomes lichenified. Ultimately, a positive diagnosis depends upon the demonstration of a pathogenic fungus from the lesion. Yeast organisms are frequently found in suspected lesions; however, Castellani⁷ doubts if they are of etiologic importance. The

number of cases in which an epidermophyton infection is limited to the vulva is small as compared with the incidence of this infection. Nevertheless, it is an important cause of pruritus vulvae and must be considered in differential diagnosis of this condition.

(c) *Trichomonas vaginalis* is a protozoan parasite which may produce a vaginitis with resulting pruritus vulvae. In this type of vaginitis the mucous membrane of the vagina and vaginal orifice are bright red, granular in appearance and covered with a profuse, frothy, thin, yellowish foul discharge. Before a definite diagnosis may be made, the parasite must be demonstrated in the vaginal exudate. This is accomplished by microscopic examination of material obtained from the deep portion of the vagina by means of vaginal speculum and small cotton applicators. The applicators which are covered with the exudate are immediately placed in a small amount of warm normal saline solution. A hanging drop preparation of this mixture of the saline and exudate should be examined while the solution is warm, because chilling stops the motility of the organisms. The organisms are recognized as motile, flagellated ameboid cells.

The degree of vaginitis produced by the infestation of the trichomonas is variable. In some patients, the vaginal discharge contains the trichomonads, but there are only slight or no subjective symptoms. In certain individuals, the rectum and bladder may be infected with the parasite, thus becoming foci for vaginal reinfection. Sayer⁷ emphasizes the importance of eradicating these residual habitats of the trichomonas. In vulvovaginitis trichomonalis, the patient complains of a burning and itching at the vaginal orifice and within the vagina and this may be severe. The copious discharge may produce a secondary dermatitis of the vulva which is more acute than that seen in chronic cases of pruritus vulvae with resultant lichenification.

An infestation by *Oxyuris vermicularis* or pinworm may be responsible for pruritus vulvae and this is especially true in children because they are affected by this intestinal parasite

more frequently than are adults. The female worms work their way out of the anus, usually at night, and may enter the vagina. In cases of pruritus ani associated with pruritus vulvae in which there are nocturnal exacerbations, particularly in children, *Oxyuris vermicularis* should be excluded as an etiologic factor. When this parasite is present, the skin between the buttocks and on the perineum is usually excoriated and a diagnosis is established by demonstrating the presence of the parasite. The gravid female worm moves from the small intestine to the rectum, where it deposits its ova, and scratching of the anus spreads the ova over the skin around the anus. Consequently, scrapings from this region will often contain the ova of the pinworm in infested individuals. The stool should also be examined for ova and for female worms.

(d) It has been definitely established that phenolphthalein, antipyrine, amidopyrine and arsphenamine may produce a fixed, localized eruption. The involved areas show periodic efflorescences and remissions of an acute, erythematous, edematous dermatitis and resultant pigmentary changes. Involvement of the male genitalia has been observed, although such cases are rare. The possibility of a fixed drug eruption—especially phenolphthalein which is limited to the vulva must be kept in mind. I have observed one case of periodic pruritus vulvae in which there was some edema and a brownish purple pigmentation of the small labia and skin in the region of the clitoris. These symptoms almost completely disappeared following cessation of the use of a cathartic containing phenolphthalein.

(e) Certain chemical ingredients of douche powders, contraceptive jellies, and vaginal suppositories will produce a vaginitis and dermatitis venenata on the vulva in susceptible individuals. Obermayer,⁸ Vaughan and Fowlkes,⁹ and Rattner¹⁰ have reported cases of *dermatitis on the male genitalia* which resulted from sensitization to the rubber of condoms. I am unaware of any recorded case of vulvitis resulting from contact with condoms; however, I feel that the possibility of this factor as a cause of pruritus vulvae should be kept in

mind. Vaginitis and dermatitis of the vulva resulting from contact with chemicals to which the patient is sensitive does not differ fundamentally from contact dermatitis elsewhere on the body. Usually, there is an acute onset at a variable time after contact with the offending agent, and edema, erythema and vesiculation depend upon the degree of inflammatory reaction which is produced. In this group of cases, an accurate history and the patch tests for suspected preparations and their various ingredients are procedures of prime importance.

(f) The exudate arising from a catarrhal cervicitis and endometritis or the irritation of urine in the presence of cystitis may precipitate pruritus of the vulva. At the onset, there may be very little visible change in the vulva; however, if these sources of irritative agents are not eradicated, continued scratching may produce the thickened, leathery skin frequently observed in these cases. If there is an associated pruritus ani, a proctoscopic examination is indicated. If a proctitis is present, appropriate treatment should be instituted. It is very difficult to evaluate the etiologic importance of cervicitis, endometritis, cystitis, and proctitis in pruritus of the anogenital region because the incidence of these conditions unassociated with pruritus is much greater than the incidence when pruritus ani and vulvae are present. Nevertheless, the discharges from these infected areas may be irritative to the inflamed surfaces of the vulva and consequently, if these conditions are present, their treatment should be included in the management of pruritus vulvae.

II. The lesions of certain pruritus dermatoses may be limited to or may involve the vulva as a part of a more disseminated eruption. The dermatoses which should be given special consideration are lichen planus,¹¹ kraurosis vulvae, leukoplakic vulvitis, and circumscribed neurodermatitis.

(a) The characteristic lesion of lichen planus is a flat, angular, shiny, violaceous, pruritic papule. Larger, raised, violaceous, scaly plaques or umbilicated papules may be present. These larger lesions will contain a reticulation of gray streak and punctae which is pathognomonic of this disease and

which is characteristic of lichen planus which involves the mucous membranes of the mouth or genitalia. The eruption of lichen planus may be fairly well localized to the flexoral surfaces of the arms, dorsum of the hands, and to the lower extremities or it may be disseminated, and in each instance the mucosa may or may not be involved. Likewise, in a small number of cases, lichen planus may be limited to the mucous membrane of the mouth or to the mucocutaneous surfaces of the female genitalia. In cases of pruritus vulvae in which such lesions occur on the vulva or involve the vaginal introitus, the whole cutaneous surface should be examined carefully for lesions of lichen planus. A rare type of lichen planus which sometimes involves the vulva is that characterized by white, angular, flat, sclerotic and atrophic papules. The surfaces of the lesions are smooth, shiny and, at times, present small, black, horny comedo-like plugs. Usually associated cutaneous lesions of the same type are found which help to clarify the diagnosis. This condition is spoken of as lichen planus sclerosus et atrophicus. This variety of lichen planus so closely resembles the late stages of kraurosis vulvae that Montgomery and Culver¹² and F. Parkes Weber¹³ have ventured the opinion that kraurosis vulvae is frequently a manifestation of lichen planus. Ketron and Ellis¹⁴ have recently added white spot scleroderma to the list of conditions which may involve the vulva which thereby produces a clinical picture simulating kraurosis vulvae or leukoplakic vulvitis. They believe that some cases which are diagnosed as leukoplakia of the vulva are examples of white spot scleroderma.

(b) Kraurosis vulvae usually occurs at the time of or following the menopause and is rarely seen in young women. It is characterized by atrophy, sclerosis or scarring, and intense pruritus. Since leukoplakia and carcinomatous degeneration are sometimes late developments in kraurosis, some authors have used leukoplakic vulvitis and kraurosis as synonymous terms. Taussig,¹⁵ Wise,¹⁶ Montgomery¹⁷ and others, however, distinguish between true kraurosis vulvae and leukoplakic vulvitis. Taussig feels that in the former

there is an atrophy of the labia minora, vestibule and tissues in the region of the urethra and clitoris. At first, the skin is red and glistening but later it becomes pale and smooth. The vaginal orifice becomes narrowed, coitus becomes painful or impossible, and itching is not necessarily a troublesome symptom. On the other hand, itching is intense in leukoplakic vulvitis, leukoplakia is a marked feature and carcinomatous development is common. A recent article by Adair and Davis¹⁸ gives an excellent description of this condition and they use the broader descriptive term, chronic atrophic dermatitis of the vulva rather than the terms kraurosis and leukoplakia vulvitis. Kraurosis vulvae should not be confused with the physiological atrophy which occurs at this time or following castration in which itching may occur, but is not so intense or severe as that of kraurosis.

Adair and Davis¹⁸ describe three stages of this disease: (1) an initial stage of itching associated with edema limited to the labia and preputial folds; in this stage there are no signs which are diagnostic of kraurosis. (2) An intermediate stage in which the skin becomes white, shiny, mottled, and early atrophic changes appear. In this stage the condition extends to the perineum. (3) A late stage in which there is marked atrophy, sclerosis, fissuring and leukoplakia.

(c) Circumscribed neurodermatitis is characterized by the occurrence of localized areas of lichenification. The itching accompanying this condition is primary and appears before any change can be detected in the skin; the pruritus is intense and paroxysmal in type. The visible changes in the skin appear later as a result of the trauma of scratching. The lesions may be irregular in outline, but frequently they are oval and vary in size from that of the palm to that of a half dollar. One or more lesions may be present which have a predilection for the nape and lateral surfaces of the neck, the extensor surfaces of the forearms, inner surfaces of the thighs and about the ankles. The central portion of the plaque is thickened and, due to accentuation of the normal lines of the skin, its surface is divided into small irregular areas on which there

may be small, dry, adherent scales. The periphery of the patch is thinner and poorly demarcated. There is no tendency to symmetrical distribution of the lesions.

The cause of circumscribed neurodermatitis is unknown. It is a common condition which occurs more frequently in women than in men, and it is found usually in the emotional, highstrung type of person. Worry, overwork, and other factors which adversely affect an unstable nervous system are important factors in the causation or exacerbation of a neurodermatitis.

This disease occasionally involves the vulva in the form of an isolated plaque on one of the large labia, or it may involve the hairy surfaces above the clitoris and extend downward to involve the labia majora. When this type of lesion is present, the areas of predilection mentioned above should be examined for plaques of primary lichenification because such associated lesions help in the interpretation of the vulvar lesion.

III. (a) The most important systemic disease of which pruritus vulvae may be a symptom is diabetes mellitus, and the possibility of diabetes must be considered in all cases of pruritus vulvae. In fact, this may be the initial complaint which causes the diabetic to seek medical advice. When a slightly elevated fasting blood sugar level is found, a glucose tolerance test should be done. Itching of the vulva may occur when the hyperglycemia is not accompanied by glycosuria, as in the case observed by McPherson¹¹; however, glycosuria usually is present. In diabetic vulvitis, there is maceration of the epidermis, with erosions, weeping and an accumulation of debris in the folds of the vulva. The urethral orifice is edematous and the patient complains of dysuria. A secondary infection occurs and in severe cases, an intertriginous and at times an impetiginous dermatitis develops in the groins and on the inner surfaces of the thighs.

(b) It is possible that systemic disturbances resulting from nutritional deficiency in rare instances may be of etiologic importance in pruritus vulvae. The anogenital region is com-

monly involved in pellagra, a syndrome which unquestionably is a deficiency disease. The possibility that pruritus vulvae may, in some instances, be a manifestation of a deficiency state is suggested by the observation of Swift,²⁰ who recently reported 4 cases of pruritus vulvae in individuals with achlorhydric anemia. In these cases, the itching disappeared following the administration of iron and hydrochloric acid. Previously, such pruritus had been considered to be of neurotic origin.

(c) It is doubtful whether food allergy is ever responsible for pruritus which is limited to the vulva. In recent years, the laity as well as the medical profession, has become so allergy conscious that both tend to overestimate the importance of food sensitization as etiologic factors in certain pruriginous dermatoses. Occasionally, we see an individual with the familiar eczema-asthma-hay fever complex who is troubled with chronic pruritus vulvae. In most of these cases, we obtain positive reaction to various foods when tested by the intradermal method; however, only a small percentage of these patients are noticeably benefited by a dietary regimen alone. This problem is a complicated one and the food allergy must be considered only as a component part. These patients frequently have signs of neurocirculatory instability, they are the victims of hereditary instabilities and constitutional inadequacies, and they are subjected to many environmental stimuli which tend to accentuate the psychoneurogenic factors which Stokes,²¹ Becker²² and Van de Erve and Becker²³ have so ably discussed. The management of this type of case must of necessity include a proper evaluation of all its phases and not be limited to a nonallergic regimen.

(d) Since pruritus vulvae occurs frequently near the time of the menopause, and since at times it is worse a few days preceding menstruation, some endocrine dysfunction has been suggested as an etiologic factor. At the menopause, there is a decrease in ovarian function and consequently, some observers have used follicular ovarian hormones in the treatment of this condition and have reported good results in a few cases.

The estrogenic hormone which has been used is that extracted from the urine of pregnant women and the commercial products which are available in this country are theelin, progynon and folliculin-menformon. It seems logical to suspect that endocrine dysfunction in some cases may contribute to the causation of pruritus vulvae, yet such an assumption for the present is largely speculative. It is possible that in the future, the endocrinologists will make discoveries which will be helpful in solving some of these recalcitrant problems.

(e) There is another group of patients in whom pruritus vulvae is the result of a psychoneurosis resulting from repressed sexual desires, marital incompatibility, masturbation, and practices resulting in ungratified sex life. Hazen and Whitmore²⁴ and Stokes²⁵ have emphasized the importance of sexual psychoses in pruritus vulvae as well as in some other types of pruriginous dermatoses.

(f) The etiologic importance of certain chronic diseases of the abdominal and pelvic viscera in pruritus vulvae, has not been established definitely. Cases in which pruritus of the anogenital region has been relieved following the removal of a chronically infected appendix have been reported. However, such cases are seen very infrequently and the incidence of pruritus which is limited to this region and which is associated with chronic disease of the viscera, is low.

Montague²⁰ has expressed an opinion that some cases of pruritus ani may result from congestion, inflammation, hyperplasia or any change in volume of a viscus which disturbs the nerves of its capsule. He assumes that afferent stimuli which arise in the capsule of the viscus are sent to the central nervous system, thereby stimulating the somatic afferent nerves by creating an irritative focus in the posterior ganglia. This irritation is then referred to the skin area supplied by the particular somatic nerve. He thinks that this is analogous in principle to misreference of pain and feels that the itching of the perineum in diabetes is primarily due to afferent stimuli arising from a change in volume of the liver or of a chronic pancreatitis. This theory is open to question; however, these

observations demonstrate the advisability of looking for evidence of chronic diseases of the abdominal and pelvic viscera in cases of persistent pruritus vulvae in which the etiology is obscure. Montague's remarks are limited to the discussion of pruritus ani, but the same theory is equally applicable to pruritus vulvae.

The most common conditions in which pruritus vulvae may occur have been enumerated. No doubt other less obvious factors are operative. A number of obstinate cases still remain in which no satisfactory cause can be found, but for the present, we must consider these as examples of primary or idiopathic pruritus.

TREATMENT

The rationale and success of the treatment which is recommended for any ailment is dependent upon a proper evaluation of the general condition of the patient and the possibility of removal of any specific or underlying etiologic factors which are discovered. Although we are unable to find a specific cause in many cases of pruritus vulvae, a thorough investigation of each case should be made before we are justified in limiting our treatment to measures directed toward symptomatic relief.

If systemic disturbances such as anemia, gout, diabetes, hypothyroidism or other types of endocrine dysfunction are present, they must receive appropriate treatment. The possibility of successful results will be greatly enhanced if the physician is capable of eliciting and correcting the psychoneurogenic factors which frequently play an important part in the causation of generalized and localized pruritus. It is important to look for signs of neurocirculatory instability, to consider the personality of the patient and her reaction to social and financial burdens.

An accurate history of the patient's sexual life is important. This phase of the problem should be discussed only after the confidence and cooperation of the patient is assured. Some difficulty may be encountered in the case of an unmarried woman; but this approach should not be neglected in cases of chronic, persistent pruritus vulvae. The manage-

ment of cases due to a psychoneurosis resulting from repressed sexual desires, marital incompatibility, masturbation, etc., must be individualized to fit each particular case.

Local treatment to the anogenital region will necessarily vary, depending upon the type of local disturbance which is present. The type of local infection and the degree of the inflammatory reaction should determine the type of treatment best suited in each case. Since intense pruritus may be relieved by topical applications which are sufficiently stimulating to substitute the sensation of pain for that of itching, we frequently see patients who are suffering from the effects of too irritative applications. Such instances of overtreatment are usually the result of self-medication or injudicious remedies advised by the physician.

Cleanliness is the first essential to proper management of pruritus of the anogenital region. Consequently, treatment of an existing cervicitis, proctitis, or cystitis must not be neglected. Cleansing douches are important and the folds of the vulva should be washed gently at least once a day. In case of acute vulvovaginitis resulting from chemicals used in the douche, the cleansing should be accomplished with soothing measures such as warm saline or boric acid solution.

Many formulae may be used for the relief of itching and each physician has his favorite remedies; consequently, in general, moist packs or soothing evaporating lotions should be used in cases of acute, edematous, vesicular or weeping vulvitis while stimulating, parasitocidal, and antipruritic ointments are indicated in the various types of chronic vulvitis. In acute cases, moist compresses of warm potassium permanganate solution (1: 10,000); Burrow's solution (1 part to 12 or 15 parts of water); warm hypertonic saline solution, or a saturated solution of boric acid alternating with applications of calamine lotion or calamine liniment with 1 or 2 per cent of phenol and $\frac{1}{4}$ per cent menthol will prove beneficial. In subacute conditions, an ointment of 2 to 5 per cent ichthylol and 1 per cent of phenol in unguentum zinc oxide may be advised.

A fungous infection usually produces a chronic or sub-acute vulvitis in which the use of stronger, keratolytic, and parasiticial agents are indicated. If the feet, groins, or the gluteal folds are involved, these areas should be treated also. There is no specific remedy for this common infection. The organism is usually confined to the epidermis, and keratolytic and parasiticial agents are indicated. Unfortunately, the tissues will not tolerate parasiticial agents in concentration sufficient to kill the fungi and therefore, the efficacy of modern treatment depends mainly upon the removal of the organism by the use of keratolytic drugs. Two of the most useful keratolytic agents are salicylic acid and benzoic acid. These drugs are most frequently used in the form of the popular Whitfield's ointment, which is a very satisfactory preparation. Full-strength Whitfield's ointment should not be applied to the vulva and the following one-half strength has been found to be most beneficial:

R	Gm. vel cc.
Salicylic acid.	9
Benzoic acid.	1. 8
Soft paraffin.	8
Coconut oil.q. s. ad 30
M. and fr. ung.	

Two or 5 per cent ammoniated mercury may be added to this ointment.

Some patients prefer a dry and cleaner type of treatment consisting of applying moist potassium permanganate packs (1:5000) for an hour twice a day, followed by an alcoholic solution of salicylic acid and benzoic acid such as:

R	Gm. vel cc.
Tr. eudbear.	1 5
Salicylic acid	3 6
Benzoic acid	4 8
Alcohol, 70 per centq. s. ad 120

After the lotion has been applied, the surfaces should be covered with the following powder:

R	Gm. vel cc.
Thymol.....	5
Salicylic acid.....	3
Boric acid powder.....	80
Talcum.....	q. s. ad 120

This type of treatment has proved to be satisfactory in many cases in which the infection involves the inguinal region. Castellani⁶ recommends Deek's ointment, which is:

R	Gm. vel cc.
Salicylic acid.....	4
Bismuth subnitrate.....	10
Mercury salicylate.....	4
Oil eucalyptus.....	4
Lanolin.....	30
Vas. alb.....	q. s. ad 100

Other parasiticial remedies may be used such as an ointment of 6 per cent sulphur and 4 per cent salicylic acid, or applications of 10 per cent silver nitrate; but regardless of the choice of remedy, the patient should be observed frequently or he should be instructed carefully in order to prevent a chemical dermatitis which results from prolonged use of these drugs. After the superficial epidermis has been removed, a bland ointment or lotion is indicated. Since recurrences are frequent the treatment may have to be repeated several times. Infected toenails should be removed and the patient must not neglect other foci such as the interdigital spaces on the feet. The intracutaneous injection of extracts of fungi such as trichophytin in an attempt to desensitize the individual to the organism has not been beneficial in a large percentage of cases.

The treatment of pruritus of vulvovaginitis trichomonalis is directed toward the eradication of the parasitic infestation. Gellhorn²⁷ recommends a dry type of treatment, using a powder of 12.5 per cent acetarsone in equal parts of kaolin and sodium bicarbonate. Sayer⁷ advises scrubbing the vagina with an alkaline solution followed by a tampon saturated with 25 per cent neosilvol and emphasizes the necessity of treating the

residual foci in the bladder and rectum. Members of our staff have found carbarsone suppositories quite effective in cases of trichomonas infection. The patient is instructed to insert one suppository each night for a month. Douches are limited to one a week and the suppositories are to be used during the menstrual period. It is impossible to give a more detailed discussion of the treatment of this condition at this time. However, it is of interest to note that Davis²⁸ has found that in cases of senile vaginitis, with an associated trichomonas infestation, the organisms disappeared following the administration of an estrogenic hormone. He, therefore, suggests that a follicular hormone be used in cases of *Trichomonas vaginalis* occurring in the postmenopausal period.

In cases in which an infestation of *Oxyuris vermicularis* is present, injections of a decoction of quassia will remove the worms from the rectum. The worms must also be removed from the small intestine by the usual procedure of a light diet and the administration of castor oil followed by santonin.

Since the etiology of lichen planus and circumscribed neurodermatitis is obscure, our treatment of these conditions is empirical. Lichen planus will frequently respond to intramuscular injections of mercury or bismuth; however, lichen planus of the mucous membranes is often very resistant to treatment. One cc. of 1 per cent bichloride of mercury twice a week or 2 grains of bismuth salicylate once a week is often efficacious in the treatment of lichen planus. The oral administration of arsenic in the form of Fowler's solution or preferably asiatic pills ($\frac{1}{10}$ grain arsenic and 1 grain black pepper) is at times beneficial in neurodermatitis. Topical applications of antipruritic and stimulating ointments should be advised. The following prescriptions are useful:

R	Gm. vel cc.
Phenol	3
Menthol	1
Camphor	3
Uns. zinc oxide	q. s. ad 30

R̄	Gm. vel cc.
Liq. carbonis deterg.....	1 5
Ammon. mercury.....	1
Ung. boric acid.....	q. s. ad 30

R̄	Gm. vel cc.
Ung. picis. liq.....	4
Zinc oxide.....	4
Starch powder.....	8
Diachylon oint.....	4
Vas. alb.....	q. s. ad 30

Roentgen therapy is especially useful in the treatment of lichen planus and circumscribed neurodermatitis. Careful consideration should be given to possible psychogenic factors in cases of neurodermatitis and sedatives such as bromides or phenobarbital are especially helpful, but should not be given over long periods.

Kraurosis and leukoplakic vulvitis do not respond to palliative measures. These conditions should be treated surgically either by section of the cutaneous nerves or by vulvectomy in cases with extensive leukoplakia.

With the rapid advances that are being made in endocrinology, it is probable that hormone therapy will prove beneficial in selected cases of pruritus vulvae. A follicular hormone should be tried in cases occurring at or after the menopause or when there is reason to believe that there is a deficiency of the estrogenic substance. Davis²⁸ obtained good results by the use of a follicular hormone in pruritus vulvae which occurred in association with senile vaginitis.

Roentgen therapy is the most valuable single aid in the treatment of pruritus vulvae, but it should be emphasized that the roentgen ray is only an adjunct to the therapy of pruritus vulvae and does not obviate the necessity of a thorough investigation of each case. In most instances, the patient experiences complete relief after three or four treatments, but in rare instances, the itching is aggravated by roentgen therapy. This type of therapy must be used cautiously to avoid radio-dermatitis. The administration of a fractional dose of one

fourth of a skin unit at weekly intervals as devised by McKee²⁹ is the technic of choice. This will give relief in many instances for weeks at a time. Recurrences of the pruritus following roentgen therapy are frequent, consequently the patient will return or consult another physician with a request for more treatment. Because of this, the dosage and technic of previous treatments should be determined before further roentgen therapy is administered. One fourth of a skin unit may safely be administered once a week for eight to ten weeks. Irritative applications should not be used in conjunction with roentgen therapy.

Vaccine therapy is of little value. It is probable that the good results obtained by Murray² and others with this type of treatment were due to a foreign protein reaction rather than to a specific effect of the vaccine. These results could probably be obtained by the use of any other foreign proteins commonly used in the form of milk preparations, one of the most common being that of aolan.

SUMMARY

Many phases of this subject have necessarily been omitted. The more common conditions which may produce pruritus vulvae have been discussed and a few therapeutic suggestions which we have found helpful have been given. The physician should consider pruritus vulvae as a symptom rather than a disease and should examine each patient thoroughly for systemic and local disturbances which may contribute toward the causation of this distressing symptom. This is an extremely complex problem and the results of our efforts are often disappointing; nevertheless a fair percentage of patients can be relieved if they are adequately studied.

THE TREATMENT OF HAY FEVER IN GENERAL PRACTICE

I. M. HINNANT AND FARRIS D. EVANS

It has been estimated that from 2 to 3.5 per cent of all people suffer during some period of their lives with pollen allergy. One may casually assume that this figure is not impressive, but considering that in a city with a population of 1,000,000 there are 20,000 people who have or who have had pollen allergy, more than a casual interest must be given to the large problem of giving satisfactory relief to these sufferers.

An increasing number of people with pollen allergy are rapidly becoming conscious of the recent strides in the allergic management of their problems. Likewise, many physicians each year are realizing the futility of attempting to give their patients satisfactory relief by limitation of their armamentarium to the various hay fever remedies, such as nose drops, coryza tablets, inhalations, ionization treatments and numerous other local surgical measures. Both patients and physicians are acknowledging the consistently satisfactory results which have been secured by thorough investigation for allergy followed by management based upon such studies. It is recognized by layman and physician alike that it is impracticable for the average hay fever sufferer to take extended and expensive trips into pollen-free areas. What then, is the proposed management of pollen allergy?

It is the consensus of opinion that the ultimate results in the treatment of patients with hay fever and asthma are dependent upon a satisfactory arrangement between the family physician and the patient. Therefore, the plan usually followed is to give complete and thorough allergy tests where

equipment and facilities are adequate and then have the patient return to his family physician for supervision of the course of treatment. If this plan were not followed, the majority of patients with pollen allergy could not entertain any thought of treatment except with the usual local nonspecific measures.

The purpose of this discussion is to present briefly the method of investigation and the plan of treatment observed in 400 patients with hay fever who were seen in the Department of Allergy during the past three years. The majority of these patients have not been under our personal care, but entered the clinic for diagnostic survey and advice as to therapy and then returned to their respective physicians for supervision of the prescribed method of treatment.

Most workers in allergy agree that the following requisites are necessary for pollen to produce hay fever and asthma:

1. The pollen must contain an excitant of hay fever.
2. The pollen must be wind-borne, as regards its mode of pollination.
3. The pollen must be produced in sufficiently large quantities.
4. The pollen must be sufficiently buoyant to be carried considerable distances.
5. The plant producing the pollen must be widely and abundantly distributed.

In Ohio and the surrounding section, there are three distinct hay fever seasons, the tree, grass and weed seasons. The tree season begins about the last week in April, reaches its height the last two weeks in May and continues through June. This produces a definite overlapping effect with the grass hay fever season. The trees fulfilling the requirements for production of hay fever are ash, black walnut, hickory, oak, poplar, elm, sycamore, birch, maple, beech, and willow.

The grass hay fever season begins about the third week in May, reaches its height the third week in June, and tapers off gradually to a nonactive stage about the second week in July. The season of 1935 was definitely prolonged due to climatic conditions, pollen being present in the atmosphere in sufficient

quantity to produce hay fever until the first week in August. Many patients, therefore, gave a history of failure to note a rest period between the grass and ragweed hay fever seasons. The grasses producing hay fever in Ohio and surrounding section are orchard grass, June grass, red top and timothy, and it is generally conceded that the latter is most abundant and produces more trouble. It is routine with many workers to use a large percentage of timothy pollen antigen and a smaller percentage of the antigen prepared from the other three hay-fever-producing pollens. Grasses other than those mentioned are, in our experience, of little clinical significance in this section of the country.

The fall hay fever season begins approximately August 10 or 15, according to weather conditions. Giant and short ragweed produce at least 95 per cent of the pollen appearing in the atmosphere during August, September and October. In Ohio and the surrounding sector, we see pollen-producing weeds which are active excitants of hay fever, but the scarcity of such weeds prevents them from being a factor in the production of clinical hay fever. In making daily pollen counts over a period of three years at the Cleveland Clinic, we have not been able to recognize and identify any type of weed pollen other than ragweed. Clinical study likewise emphasizes the fact that immunization to ragweed antigen produces excellent clinical relief if other allergy is controlled. We routinely include in our studies, pollen tests for goldenrod, English plantain, *Chenopodium*, marsh elder, Sorrel family, Russian thistle, cocklebur, corn, wheat, rye and we often note reactions, but no direct relationship to the patient's problem can be established.

During the past three years, we carried out daily pollen counts according to the standard method adopted by Mr. O. C. Durham, Chief Botanist, Abbot Laboratories. These daily counts have been of extreme value in interpreting hay fever symptoms during the active season. Likewise, they have been valuable in attempting to regulate the dosage of pollen antigen during the hay fever season, particularly in the patients who

were treated by the coseasonal method, when doses of antigen are necessarily very small and injections frequent. The greatest value of daily pollen counts is knowledge concerning the plants producing pollen in the surrounding section as well as the type, abundance, time of appearance and disappearance of pollen in the atmosphere.

APPROACH TO ALLERGIC PATIENT

One immediately raises the question of proper approach to the problem of the patient with pollinosis. One dictum deserves emphasis—each patient with allergy must be individualized, both in regard to investigation and to treatment. Workers in allergy recognize the importance of standardized, reliable, potent extracts for skin testing, and they agree that such study is dependent upon minute detailed searching and that considerable time and effort are necessary to secure satisfactory results. The average physician feels that he cannot afford the outlay of materials for allergy investigation, nor does he have time for complete allergy investigations. Failure usually results when investigation is carried out with a limited number of allergens that were purchased as a special offer by some commercial supply house, and again failure in therapy results in the average patient who has received the 12, 15 or 20 injections supplied by the commercial house as an adequate pre-seasonal method of pollen hyposensitization. It is therefore imperative that further plans of study and treatment in these hay fever and asthma sufferers are necessary. We believe that the results gained by the concurrent efforts of a completely equipped diagnostic unit with the patient's private physician should result in an increase in the number of patients who secure satisfactory relief of symptoms.

The all-important question of etiology reaches a pinnacle in the consideration of seasonal hay fever and asthma. Frequently the multiplicity of offending factors and the determination of their relative importance is the keynote in the plan of treatment. There is no substitute for complete and thorough

investigation of these patients, and we feel that a definitely higher percentage of good results will be the reward if this procedure be made imperative.

A carefully detailed history relative not only to the present illness but also a general systemic review, should always be recorded. By contact with a large number of patients and a constant review of their histories, one realizes the many and varied factors which may influence the future health of the hay fever patient. If these essentials are recorded in a carefully taken history, they serve as the guide posts to the most advantageous procedures to be followed in the solution of the individual's problem. Every patient should have a complete physical examination, routine laboratory work which includes a red and white blood cell count, a differential count, blood Wassermann, blood sugar determination and urinalysis. The red blood cell sedimentation rate is indicated if any suspicions are aroused that an infectious process may be present in conjunction with the allergic state. The close relationship between the upper and lower respiratory tract in itself justifies a routine x-ray examination of the chest. Consultation with a nose and throat specialist and the conservative corrections of obstructive nasal conditions should never be omitted. Mechanical barriers such as a deviated septum, spurs and nasal polyps will prevent a satisfactory response to immunization. It is true that no intranasal surgery should be carried out until the allergy is definitely under control, but after control is established, any opportune time may be elected for well-chosen surgical procedures.

The choice of the method of skin testing is a matter to be decided upon by the allergist after the completion of the preliminary examination. Some workers limit themselves to only one technic while others use both the scratch and the intracutaneous methods. A certain number of skins "flare" to all substances used intracutaneously and therefore it is impossible to interpret reactions. There are also a number of skins which fail to show any reaction whatever to the scratch method and necessitate the use of the intracutaneous technic.

THERAPEUTIC METHODS

In pollen allergy, sensitivity to pollen is the largest factor. Only a few patients have the opportunity of visiting pollen-free areas and it is obvious that one cannot eliminate the pollen of hay-fever-producing trees, grasses, and weeds. Desensitization to the specific offending pollen therefore is imperative. Is it acknowledged among workers in allergy that pollen desensitization by the accepted methods will give 90 per cent of sufferers an adequate relief of symptoms? What methods are to be adopted to carry out therapy which results in such excellent clinical relief? It has been noted previously that each patient must be individualized, both as to investigation and to therapy. Complete survey of the patient's problem is necessary; this includes not only tests for pollens of suspected trees, grasses, weeds, but also a careful interpretation of the allergens other than pollen, and strict adherence to the prescribed routine of elimination or desensitization. Occasionally, we have seen a patient with seasonal hay fever and asthma who could not be desensitized, but who had very little discomfort during the pollen season because he had strictly eliminated all epidermal, inhalant and food substances to which he was found sensitive. This is not the method of therapy to be advised, but it does illustrate the point that allergens other than pollens play a part in the production of patients' symptoms. For this reason, we stress the advisability of a strict allergic regimen, particularly before and during the active hay fever season.

Three methods of therapy may be used in desensitization procedures—coseasonal, preseasonal, perennial.

Coseasonal Desensitization.—The patient who is seen at the onset or in the middle of the hay fever season and who has had no form of therapy presents a difficult problem. For many years, it was considered undesirable to begin treatment during the active hay fever season, but in recent years, many workers have adopted a plan of coseasonal treatment which is devoid of any danger to the patient, and results in satisfactory relief of symptoms in from 60 to 70 per cent of the cases. The

first procedure with the untreated patient suffering acutely with hay fever and asthma is to completely investigate the allergy, prescribe a strict routine, limit activities, prescribe mild symptomatic measures and institute very small doses of pollen antigen at frequent intervals. The doses of pollen antigen under these circumstances deserves more than a casual note. The initial dosage should be from 5 to 30 pollen units (0.05–0.3 cc. 1:10,000 solution) with repeated injections at one- or two-day intervals, gradually increasing the dosage to not more than 80 to 100 pollen units. As the season advances, an optimum dosage of 150 or 200 units may be used, but in our practice, we never use more than this amount. Such minute doses of antigen given two to three times a week will result in excellent relief of symptoms. More care should be exerted and smaller dosage should be administered if one is dealing with hay fever and bronchial asthma. The asthmatic tends to get an overdosage very easily, with consequent intensification of symptoms.

Preseasonal Desensitization.—Most physicians use the preseasonal method of desensitization. The patient reports to the physician two, three, four or five months before the expected hay fever season begins. Allergy tests are made and treatment is carried out with pollen extract based upon the patient's history, results of skin tests and knowledge of the patient's environment. Treatment is instituted with small doses of pollen antigen, 10 to 30 units and the dosage is increased at each injection unless an undesirable reaction is obtained, until an optimum dosage is reached for the individual patient. This is usually between 3000 and 6000 units of pollen antigen. With the onset of the hay fever season, the dosage is decreased to approximately 2000 to 3000 pollen units, and maintained at this level until the active pollen season ends. The inoculations are given at intervals of twice a week until a substantial dosage is obtained and then continued at weekly intervals until the close of the hay fever season. With the preseasonal method of treatment, excellent results are obtained in from 70 to 80 per cent of cases.

Perennial Desensitization.—Today, many workers are advocating the perennial method of desensitization in the treatment of pollen allergy. A close analysis of opinion concerning this method discloses no points of disfavor and many advantages. Briefly, the advantages may be stated as follows:

1. Intensive preseasonal or coseasonal treatment is avoided.
2. The tendency toward unfavorable local or systemic reactions is decreased.

3. Contact between patient and physician is established and maintained throughout the year. The value of this feature can hardly be overestimated. Many deviations of a patient's health from normal may be corrected in the early stages if he is under the close observation of a physician. We have also found it opportune in a number of patients taking the perennial method of therapy to institute other measures of desensitization, particularly to house dust in the domestic and to bacterial vaccines in the patients who exhibit a definite tendency to upper respiratory tract infections during the fall, winter and spring seasons. Because of climatic conditions during winter months, Cleveland and the surrounding sector offer splendid opportunities for therapeutic measures directed toward controlling respiratory conditions. Every effort expended in this direction promises a more normal state of health and, indirectly, more satisfactory results with allergy control.

4. Treatment may be instituted at any time of year; this enables the physician to distribute his work more evenly throughout the year and to avoid a preseasonal or coseasonal rush of hay fever sufferers.

5. Perennial desensitization permits the patient privileges of vacation and travel. Most patients seek vacation during the summer or early fall months when pollen is heaviest in the atmosphere. The perennial method of therapy presents a convenient aid to the patient in this respect.

6. The final point of advantage and probably the one of greatest significance in control of pollen allergy, is that the perennial method of desensitization offers some promise of a permanent immunity. One does not work with hay fever and

asthma patients for any length of time before he realizes that this is the point of interest to the patient. That permanent immunization can be effected in a large percentage of patients if thorough and consistent therapy is carried out is beyond any pale of doubt. Walker¹ reports cures in 26 per cent of his patients after preseasonal treatment extending over a period of years. If excellent results are obtained with preseasonal desensitization over a period of years, perennial treatment should yield equally good or superior results. Observation of a large group of patients receiving the perennial method of therapy over a period of years will answer this question.

A certain percentage of patients with pollen allergy report for allergy investigation during the fall and winter seasons for hay fever, asthma or some other allied allergic state and begin the perennial method of therapy. However, the majority of patients enter the all-year method of treatment after an intensive preseasonal or coseasonal course of therapy has been followed. Instead of discontinuing dosage, the patient continues to take pollen antigen injections at weekly intervals, the dosage being gradually increased to a maximum level which may be any amount between 3000 and 30,000 pollen units, depending upon the individual case. It is agreed that the results in an individual problem do not depend upon giving a large amount of pollen antigen, but rather upon the reaction of the patient to immunization procedures, regardless of the amount of antigen employed. Injections are best continued at weekly intervals through the first year of therapy. Less frequent intervals may be employed in the late years of pollen therapy, but the interval should never be greater than two weeks. In this respect, we differ with the commercial supply houses, who are extensively advertising their pollen extracts for the perennial method of desensitization, and advising that injections be given once a month. Satisfactory immunity cannot be obtained with such infrequent injections.

Certain points should be emphasized in regard to the technique of pollen therapy. Too severe local reaction or any sign of symptom of systemic reaction should be avoided. Signs and

symptoms of constitutional reaction indicate shocking of the tissues and not stimulating immunity. It is far more advantageous to give a subreaction amount of pollen antigen throughout the course of therapy than to encounter one general reaction. If such a reaction occurs, the dosage should be decreased to a safe level, several injections of this amount being given and then the dosage should be gradually increased again.

The possibility of giving the pollen extract intravenously should be avoided. By careful aspiration of the syringe after the needle is placed in subcutaneous tissues, this possibility as a rule, can be entirely eliminated, but occasionally an error in overdosage is made. Immediately, a tourniquet is placed above the site of injection; a 1:1000 solution of adrenalin is injected in and about the site where pollen antigen was given and small amounts of epinephrine are injected into the opposite arm. After a few minutes, the tourniquet is slightly loosened for a few seconds and then reapplied. The tourniquet is alternately tightened and loosened for a period of thirty minutes, permitting small broken doses of antigen to reach the vital tissues. The patient should be kept under observation for a period of two or three hours, and if discharged, very complete instructions should be given to the patient or relative for the use of adrenalin in case a delayed reaction occurs in six, twelve or twenty-four hours. Many serious reactions can be avoided by the use of this simple technic.

Patients who have received injections of pollen antigen should be kept in the office for twenty or thirty minutes in order to observe and control any constitutional reaction. If reactions are to be noted, they will usually occur in this period of time.

The question of securing potent and reliable pollen extracts for testing and treatment purposes arises. Many commercial supply houses offer perfectly satisfactory antigens in standardized dilutions for therapy in the average case. The antigens are usually prepared in groups, such as the "Spring type," the "Fall type" or a mixture of the two. One immediately recognizes the limitations of this type of therapy and the lack of

individualization for each allergic patient; furthermore, no complete allergic survey has been made, and no correlation is possible between the clinical history and suspected allergens. It is conceivable that any method of therapy directed along these lines would result in satisfactory relief in the average patient, but would fail in the patients whose conditions deviated from the normal.

Many physicians have availed themselves of diagnostic allergy units whereby complete investigation may be carried out, treatment sets of pollen antigen may be prepared according to correlation of clinical history, skin reactions to pollens, and a thorough knowledge of the pollen flora in the patient's environs. In this way, not only are more accurate methods used in planning therapy, but the patient is given the opportunity of availing himself of knowledge concerning his own allergic state, and regarding allergic factors discovered in testing, and he is also stimulated to study his allergic problem. Practically all workers in allergy prepare their pollen extracts and supply treatment sets to the family physician; these are accompanied by detailed instructions regarding the administration and suggested schedule of dosage. Such a plan of cooperation between the allergist and family physician assures the patient of keener interest in his problem and ultimately, of more successful relief of symptoms. In the past three years, we have followed this plan of cooperation with the family physician in more than 300 patients. Results in this group of patients have been very gratifying, and a high percentage have secured satisfactory relief of symptoms. It is needless to state that the average hay fever sufferer is dependent upon his family physician for ultimate control of his problem and we believe the results obtained by the concurrent and cooperative efforts of a central diagnostic allergy unit with the patient's private physician will lead to a better knowledge and control of the pollen allergy problem.

Regardless of every effort, a certain percentage of patients will be found who have discomforting hay fever and asthma symptoms during the most severe days of the pollen season.

A discussion is incomplete without some mention of measures to afford relief of the acute symptoms.

If the patient has rather acute symptoms, the following measures should be considered. Limit activities, avoid undue exercise, heat, fatigue, stay out of the country, off golf courses, by all means avoid swimming and do not drive more than necessary. Eat lightly, carefully check the diet for known or suspected food allergens. If any uncertainty exists, eliminate common food allergens such as wheat, eggs, milk, potatoes, tomatoes, etc. Insist on normal gastro-intestinal elimination. Avoid flowering plants; check house for any possible flowers and remove these and have the room thoroughly cleaned. Avoid contact with house dust and smoke-congested rooms. Remove from environment any known or suspected epidermal or inhalant allergen. Beware of cosmetics, use the nonallergic brands of cosmetics that can be obtained at any good pharmacy. In effect, keep in mind that any substance may be aggravating the patient's symptoms.

Drug therapy is necessarily limited, and when employed should be mild.

Eye drops of the following composition are helpful:

R	
Holocain hydrochloride.....	gr. ii
Zinc sulphate.....	gr. $\frac{1}{2}$
Adrenalin 1 : 1000.....	3 i
Distilled water.....	q. s. ad 3 i

Sig. 2 to 3 drops in each eye three to four times a day.

Eye washes of boric acid solution or normal saline serve to relieve the average sufferer. If edema of the conjunctiva is marked, 10 drops of a 1:1000 solution of adrenalin added to an eyecup of normal saline solution gives good relief. Shaded glasses are quite helpful. Ice-water compresses applied to eyes several times daily will allay irritation and give a sense of comfort.

The nasal passages are best untreated unless symptoms are severe. In this case, a nasal spray of 1 per cent aqueous solution of ephedrine sulphate with 5 grains of metycaine to 1

ounce, is helpful. If the patient is irritated by ephedrine, it is best to resort to a weak solution of cocaine, such as 2 per cent cocaine hydrochloride which is used as a nasal spray. Under no circumstances is local nasal medication to be used unless the patient's discomfort demands such therapy. Oily solutions such as nose drops are as a rule irritating. It is always advisable to use an atomizer in order to secure a more uniform distribution of the medicament to all surfaces.

For oral administration, preparations of ephedrine, atropine and aspirin are commonly used. Before prescribing drugs, the patient should be carefully questioned as to knowledge of any drug sensitivity. It is easily recognized that oral administration of any drug in doses that will not produce toxic effects can be of only limited value to the patient who has severe hay fever or asthma. In our experience, drug therapy by the oral method is of little value, although one may find the exceptional patient who responds nicely to small amounts of the drugs mentioned above.

When the patient with pollen asthma is acutely ill, bed rest is imperative. All of the preceding cautions should be exerted fully, particularly the necessity for a liquid or light diet, plenty of hot drinks, good gastro-intestinal elimination, care of any possible inhalant or food allergens. Ephedrine or ephedrine and amytal may control the paroxysms. The use of a 1:1000 solution of adrenalin hypodermically, as necessary, or the use of the newly marketed adrenalin 1:100, inhaling the fine mist from the nebulizer is indicated in the more severely ill patients. There is no advantage in withholding adrenalin, permitting the patient to suffer one paroxysm after another because this tends only to exhaust and weaken him. A small dose given in the early stages of an attack will prevent many severe paroxysms. In our experience, morphine is usually disastrous, atropine is contraindicated in almost 100 per cent of the cases, and iodides are of questionable value in the acute stage. The same is true of preparations of calcium. Mild sedation is indicated in the average patient since it removes some of the restlessness and anxiety. The best form of therapy

is the institution of investigation and control of the patient's allergic problem to prevent such a recurrence in the future.

CONCLUSIONS

1. The treatment of hay fever in general practice should be under the direction of a well-trained allergist.
2. The patient should have a complete and thorough investigation.
3. The general practitioner is the ideal connection between the central diagnostic unit and the patient with hay fever.
4. A plan is outlined which has been a great aid in gaining the close cooperation of the patient.
5. The most common cause of failure in the treatment of hay fever is the presence of other unrecognized sensitivities in the patient.
6. The innumerable forms of nonspecific therapy are rapidly being discarded with the further development of specific treatment.
7. The early inauguration of the allergic management of patients with hay fever offers the only assurance of the control and prevention of bronchial asthma as a complication of hay fever.
8. The three methods of treatment of pollinosis are discussed—coseasonal, preseasonal and perennial. Our observations lead us to believe the perennial method to be most efficient.

FOOD ALLERGY IN MILD AND SEVERE CYCLIC VOMITING

I. M. HINNANT AND L. J. HALPIN

IN 1882 Gee¹ published a paper entitled "On Fitful or Recurrent Vomiting" and presented the results of his studies of 9 children suffering with this condition. His opening statement may well be quoted: "These cases seem to be all of the same kind, their characteristic being fits of vomiting, which recur after intervals of uncertain length." Little did he perceive the interest and study that this symptom-complex would command in coming years, nor the controversy that has arisen among workers concerning etiologic factors. Gee described the outstanding symptom, vomiting, and noted the lack of periodicity of attacks. He also called attention to the presence of clay-colored stools during the attacks in some cases.

Recurrent vomiting is classified as a disease of the stomach by many textbooks. It is not a disease, particularly not of the stomach, but it is a symptom-complex in which the majority of symptoms are manifestations of gastro-intestinal disturbances, the etiology of which is obscured by the lack of knowledge concerning the assimilation of faulty metabolic products, the mechanism of absorption and the means by which such a profound toxemia is produced in the body. That recurrent vomiting in children is a result of a profound toxemia is supported by many points, evidenced by symptoms, physical findings and the clinical course of the patient.

Cyclic or recurrent vomiting occurs frequently, although the true nature of the condition often is not recognized. The condition is characterized by recurring attacks of vomiting, which occur at regular or irregular intervals of days, weeks, or months, being initiated without any adequate exciting cause,

and terminating spontaneously, leaving the patient in a state of profound prostration. The duration of the active stage characterized by vomiting, fever and prostration is usually one, two or three days, although the prodromal period and the period of recovery lengthens the attacks to three, four, five, six or seven days.

This condition occurs with equal frequency in boys and girls. The onset is usually between the ages of two and four years, but may date back to infancy. The physical characteristics are often distinctive, denoting a delicate constitutional make-up, a highly nervous temperament and a tendency to lack of muscle tonus with increased vasomotor reactions. Much has been said of the inherent neurotic tendencies indicating characteristics as noted above. Certainly, one can recognize a more sensitive, nervous response in these children, and often one can elicit the possibility of a functional background in the parents.

The symptoms are typical. The prodromal stage is characterized by anorexia, lassitude, rings under the eyes, irritability and a sense of discomfort in the epigastrium. After a period of from twelve to twenty-four hours, there occurs the active stage of extreme nausea, vomiting, elevation of temperature, prostration, abdominal discomfort, constipation or diarrhea. Vomiting occurs at frequent intervals, usually from one-half to every three or four hours. The vomitus is usually composed of mucus, it is stained deeply with bile and occasionally it is blood-streaked; this apparently is due to the violent emesis. The temperature is elevated and may rise to 104° or 105° F. Within twelve to twenty hours, the exhaustion is quite marked, dehydration is noticeable, and stupor is apparent. Then recovery begins, but is drawn out over a period of a few days, this stage being marked by apathy toward food and by fatigue and languor. Between attacks, the child enjoys normal health except for mild gastro-intestinal symptoms such as epigastric cramps and constipation, fatigue, and a constantly variable appetite.

Physical findings other than prostration, fever, dehydra-

tion, tachycardia, hyperpnea and pallor are few. The abdomen is usually distended early in the course of an attack, but later it is flat, exhibiting generalized tenderness due to violent emesis more than to gastro-intestinal pathology. Examination of the stools in some cases reveals a lessened bile content; mucus is noted occasionally and rarely are there any evidences of blood. Laboratory studies give results of a consistent nature. Leukocytosis is a constant finding. Hypoglycemia, lowering of the bicarbonate content of the plasma, and acetone bodies in the blood and urine have been reported. The urine is necessarily scanty. All findings return to normal with cessation of symptoms and the child progresses in a normal manner until the advent of a similar attack.

Analysis of symptoms in a child with severe cyclic vomiting suggests more than a casual relationship between this symptom-complex in childhood and the occurrence of migraine in the adult. In our series of cases, hemicrania was not an infrequent symptom. In the older children, gastro-intestinal symptoms became less severe and cerebral symptoms more marked in direct relationship to age. In a recent review of cases of migraine, some of the patients gave a history of recurrent attacks of vomiting in early childhood. A more carefully elicited history would probably reveal that an even greater percentage of patients experienced such a symptom-complex in childhood.

No effort is made to explain the mechanism by which protein substances reach the tissues. That there exists some undemonstrable biliary dysfunction permitting the passage of unsplit protein substances into the blood is without question. It is likewise conceivable that there exists an increased permeability of the intestinal mucosa, and with any degree of intestinal stasis or reverse peristalsis, an overload of nonsplit protein substances or faulty metabolic products is thrown into the circulation, reaching the tissues as toxins and producing a violent reaction. That cyclic vomiting is a result of severe toxemia is beyond pale of doubt. The prodromal period marked by anorexia, restlessness, irritability, languor, the early

appearance of fever, the active state characterized by epigastric discomfort, gaseous distention, cramps, colic, often diarrhea, nausea and extreme emesis which lasts from twenty-four to forty-eight hours, and the final stage, with severe exhaustion and profound prostration followed by a slow and gradual return to a normal state within a period of several days, strengthens the contention that such a clinical picture could only result from severe toxemia. What part food allergy plays in influencing the precipitation of this chain of symptoms, or food allergens in rendering the intestinal mucosa permeable to the passage of toxic products to the tissues cannot definitely be determined at this time. Our studies lead us to believe that severe cyclic vomiting is largely influenced by food allergy and relief of symptoms can be obtained with control of allergy.

Because of the results which we have secured in the treatment of 20 patients with cyclic vomiting, we desire to report our findings and to emphasize the importance of food allergy in the production of this symptom-complex.

These patients were referred to the Allergy Department because of the major symptom-complex of recurrent vomiting or for investigation of associated conditions that were thought to be due to allergy. It is interesting to note that a number of these patients were referred from other departments in the clinic, impressions or diagnoses having previously been established without a consideration of recurrent vomiting. Two patients were referred from the Genito-Urinary Department because of impressions that led to diagnoses of recurring pyelitis. Complete investigation between and during attacks did not suggest any connection between the genito-urinary tract and the symptom-complex. Following a complete allergy investigation, a regimen based upon the results of the allergic studies gave complete relief from symptoms. In one case, a diagnosis of intermittent gastro-intestinal obstruction had been made. Complete survey of the patient's problem including roentgen study of the gastro-intestinal tract did not suggest any definite lesion but complete relief was secured following the institution of a regimen based upon the results of our

studies for allergy. A few of these cases were seen originally in the Department of Ophthalmology because the parents believed that eye pathology, particularly ocular muscle imbalance, could produce the symptoms noted. The majority of patients were referred for allergy investigation after other causes had been excluded and in the belief that food allergy might be a large factor in the production of symptoms.

Certainly, the most valuable aid in establishing a diagnosis of recurrent vomiting is a carefully elicited history. The history must include a thorough summary of the nature of the attacks, their frequency, the physical state during and the condition of the patient between attacks, faulty eating habits and any tendency toward nervousness or environmental factors which might have a bearing on the present illness. No less important is the careful inquiry into the frequency, severity of recurring respiratory infections and their relation to attacks. Our experience leads us to believe that respiratory tract infections play a minor rôle in precipitating attacks. A complete review of symptoms which may be due to disturbances in the various systems will be of further aid in establishing or excluding any possible causative influences. We believe that the clinical picture is a very definite one, and that if one follows the trend of symptoms as noted above and evaluates the characteristic physical findings, errors should not be encountered in firmly establishing a correct diagnosis.

A painstaking history regarding the possible presence of allergy, particularly food allergy, is imperative and through this, one may obtain knowledge as to whether or not the patient is an allergic individual. Such positive information is strengthened by the presence of a strong family history of allergy. Certainly, a review of the personal and family history for the presence of any known allergy which is producing cutaneous, cerebral, respiratory or gastro-intestinal tract manifestations will add greatly to the information concerning the nature of the patient's illness and further knowledge relative to causative factors.

The carefully elicited history and thorough physical exami-

nation usually enable the observer to establish a definite diagnosis. However, in a certain percentage of cases, questions arise concerning the possibility of organic lesions, particularly of the genito-urinary and gastro-intestinal tracts. In such instances, more thorough and complete examinations by *x*-ray and other laboratory procedures are necessary to exclude these factors. Likewise, examination of the eyes, roentgenograms of the chest, and any other studies which will exclude any conditions exerting a direct or indirect influence should be performed. In our studies, we include complete examination of the blood, blood sugar, blood Wassermann, urinalysis and often red blood cell sedimentation rate, if there is any suspicion that an infectious process is present.

TESTS FOR ALLERGY

It is customary to employ the scratch method of testing for allergens in the majority of cases. By the use of this method, sufficient information may be obtained in a small percentage of patients and certainly one avoids any dangers of constitutional reaction. Workers in the field of allergy grant that only a small percentage of patients will exhibit positive reactions to allergens by the scratch technic, and this is particularly true in patients in whom food allergy is the major problem. In the group of children of sufficient age to permit use of the intracutaneous technic, further investigations with direct testing usually give sufficient information regarding causative factors. We have not experienced poor and unreliable results in testing for food allergy as some workers have stated, but find our results most promising.

In many patients who present the symptom-complex of recurrent vomiting, the age, or mental or physical qualities have prevented the direct methods of testing. In this group of patients, the indirect or passive transfer method of testing becomes indispensable. In our experience, the passive transfer method has been of greatest value where the following conditions exist:

1. In children where physical and mental shock render direct methods of testing inadvisable.

2. In patients with severe cutaneous lesions, where extensive involvement and often lichenification of skin renders sites of injection impossible.

3. In the group of patients who present a generalized hypersensitive, nonspecific response to any substance applied. This response probably is due to trauma and release of histamine-like bodies locally and it is not infrequently seen in cases of eczema and urticaria.

4. In the acutely ill patient.

The passive transfer method of testing presents no technical difficulties. By taking sufficient blood from the allergic patient to be tested; we do not experience any limitation of tests, but on the contrary find opportunity to check questionable or suspected allergens repeatedly. It is obvious that infinitely more time, detail, and flawless technical work is involved in such a procedure. In the 20 cases of recurrent vomiting presented in this discussion, investigation for allergens was carried out by the passive transfer method in 10. Our findings with this indirect method of testing indicate that the results have been equal to or superior to those secured by the direct method of testing.

Finally, one may necessarily use all 3 methods of testing for allergens in order to obtain sufficient information concerning the allergic reactions. Seldom does this combination of methods result in failure, but if such an instance occurs, further investigation through food diary, elimination diets of individual or stock type, and the use of the digestive leukocyte response, as recommended by Vaughn,² gives information which is of undeniable value.

Twenty children with severe cyclic vomiting have been treated since January, 1934 and it is interesting that this group comprises 10 per cent of the total number of children treated for allergic disease during this period. This fact, in itself, impresses one with the frequent occurrence of this condition.

The average age of our patients was seven and one-half

years. In several of these patients, symptoms had been present since infancy, and in others the complaints had appeared comparatively recently, the average duration of symptoms being three and three-fourths years. The positive family history of allergy which was found in 13 or 65 per cent of these patients is approximately the same as that in any allergic condition occurring in children.

Fifteen or 75 per cent of the patients with cyclic vomiting exhibited clinical manifestations of allergy. These were allergic rhinitis, asthma, urticaria, allergic conjunctivitis, and eczema. The diagnosis in these cases can usually be established by a carefully elicited personal and family history, physical examination and allergy investigation.

Complete and thorough skin tests with from 120 to 150 extracts were carried out. In 10 or 50 per cent of the cases, the passive transfer method was employed. In cases where limitation of testing was encountered, we have found that the group type of food extracts is valuable.

The physical findings, at the time of the patient's visit to the clinic were negative in 14 instances. Of these 14 patients, diagnoses of pyelitis had been made previously in 2 instances. During the time these 2 patients have been under our observation, no evidence either by laboratory procedures, roentgen examination or complete genito-urinary investigation has been revealed which would substantiate such diagnoses.

Physical examination revealed evidence of associated pathological conditions in 6 or 30 per cent of the total number of patients with cyclic vomiting. Three of these patients had hypertrophied tonsils and adenoids, 1 was suffering from malnutrition, 1 had rickets, and 1 had a deviated nasal septum. In only 7 of these patients, or 35 per cent, did we find it necessary to employ complete gastro-intestinal roentgen studies to exclude any possible organic lesions, and in each of these seven cases, the findings were normal.

The routine laboratory tests were employed. In 9 of the 20 patients, or 45 per cent, the blood eosinophilia varied from 2 to 11 per cent.

It is of interest to note the foods to which these patients were found to be sensitive. As in other allergic states due to food allergy, the foods commonly included in the daily diet are identified as causative factors. Milk, grains—particularly wheat—eggs, white potatoes, chocolate, beans and peas, tomatoes, spinach, bananas, apples and oranges were noted as causative agents in the order named. In no instance was one food alone recognized as the offending substance, although in several instances, the clinical history and the degree of skin reaction definitely indicated that 1, 2 or 3 foods were major offenders. Our efforts in dietary control have been directed toward complete removal of all offending substances for a strict trial period which varied from three to six months, depending upon the individual problems. After clinical relief is obtained, a more liberal type of dietary management is permitted. Such a procedure shows promising clinical results.

Elimination of offending food substances from the patient's diet is one phase of management. Adequate and palatable substitutes is another and deserves more than a casual thought. In outlining the regimen for the allergic patient, we believe that minutely detailed instructions concerning adequate substitutes, planning of menus and recipes for the preparation of palatable dishes are indispensable. In this respect, we utilize the facilities of our Dietary Department and have received favorable encouragement from the patients and parents as well. Certainly, we feel that too much stress cannot be placed on this phase of the problem. When milk is eliminated, not only are suggestions given regarding adequate caloric replacement, but directions are given for the inclusion of generous quantities of calcium, phosphorus and vitamins A and D as long as milk is withheld from the diet. When wheat is eliminated, it is necessary not only to provide adequate and palatable breadstuffs from the grains permitted, but also to insure a sufficient intake of vitamin B through the concentrated vitamin B products. The elimination of wheat curtails the intake of whole grain cereals, one of the largest sources of vitamin B in the child's diet and therefore, these protective substances must be supplied. Our clinical results indicate that these pre-

cautionary measures are of infinite value in providing protection from conditions which are attributed to dietary deficiency.

The treatment instituted for these 20 patients was strict management based on the results of allergy studies and correction of any associated condition that bears a direct relation to the patient's problem.

General hygienic measures with adequate and nutritious diets are employed and normal gastro-intestinal elimination is emphasized. It is of the utmost importance to supply a well-balanced diet with the proper amounts of carbohydrates, fats, proteins, vitamins and minerals to insure proper nutrition and growth while eliminating those foods to which the patient is allergic.

The results of the treatment of cyclic vomiting in these children indicate that food allergy is a large factor in the production of the condition in a high percentage of patients. In 13 patients, or 76 per cent, excellent results were secured, 4 or 24 per cent showed improvement, and in three instances the patients did not cooperate with us. Therefore, all the patients who have followed the allergy regimen have noted excellent or good results.

SUMMARY

Recurrent or cyclic vomiting in children is a condition which has been attributed to many etiologic factors.

Our results in a small series of 20 cases lead us to believe that in all instances, it is influenced by food allergy.

We feel greatly encouraged with the results secured in this group of 20 patients with cyclic vomiting and wish to further our observations over a greater length of time and in a larger series of cases in order to evaluate more fully the significance of food allergy in the etiology of this condition.

THE TREATMENT OF BURNS

GEORGE CRILE, JR.

THE three considerations which should guide our choice of treatment for a burned patient are: (1) the immediate mortality, (2) the permanent disability, and (3) the comfort of the patient. Certain methods of treatment have special merits which make them particularly advantageous in certain types of burns, and in each case, the appropriate treatment should be given so that the patient may not only be rendered comfortable, but may be assured the maximum safety and the minimum permanent disability.

I. CAUSES OF DEATH FROM BURNS

It has been well established that there are three distinct phases in the patient's reaction to an extensive burn. The first phase is marked by the initial shock and by the diminution of blood volume secondary to loss of plasma from the burned surface. The second phase becomes apparent at the end of the first day and as Aldrich¹ has showed, is associated with the appearance of streptococci in cultures from the burned areas and is marked by a rising temperature and evidences of severe toxemia. The last phase usually begins about the seventh day and is characterized by a temperature indicative of the presence of sepsis which is secondary to accumulations of pus beneath eschars or necrotic tissue.

Glover,² in reviewing a series of 310 cases of burns, observed no fatalities after the fifth day. In other words, the third or septic stage is not dangerous to life, although as we shall see later, it may be the most dangerous stage in respect to permanent disability.

Death during the first five days following a burn comes either (1) as the result of the initial shock, (2) as the result of changes in blood volume, blood concentration and blood chemistry, or (3) as the result of toxemia due to absorption of bacterial toxins and products of tissue destruction in the affected areas.

Davidson³ and others have shown that in the presence of extensive burns, the blood chlorides are consistently lowered and reach their lowest level at about the fifth day. This, Davidson believes, is due to two factors: (1) loss of chlorides in the exudate and (2) an actual retention of chlorides in the tissues. In addition to this, it has been shown by many workers that there is a marked concentration of the blood, the hemoglobin not infrequently rising to 180 per cent, and the other blood constituents, both chemical and cytological, undergoing a corresponding concentration. The nonprotein nitrogen level of the blood rises, not only as a result of concentration, but also as a result of actual nitrogen retention. This retention is probably largely due to the low blood pressure and the diminished blood volume during the initial stage of the burn, but it may also be the result of actual kidney damage due to absorption of bacterial toxins or products of tissue destruction.

The phase of toxemia which follows the initial shock is, as a rule, the most critical period. The temperature rises daily and finally strikes a high plateau which is accompanied by great prostration or delirium. Examination of the blood shows that it has not returned to normal before this phase appears, and generally the patient is exhausted from the shock of the first day and poorly fitted to withstand a severe toxemia. But as the end of the first week approaches, the temperature curve begins to become septic in character with morning remissions, and the general condition of the patient rapidly improves.

II. PERMANENT DISABILITY FROM BURNS

There is no more pathetic sight than the needless deformity of a child with the contracted scar of a burned neck pulling the chin downward to the chest wall, distorting the teeth and jaw.

and limiting the movements of the head. Most of these deformities can be avoided if the burn is given prompt and adequate treatment with consideration for the end-result and not merely for the patient's immediate comfort and well-being. The contracted scars of burned hands, axillae, face, and neck are most apt to produce serious and permanent disability, but a burn on the surface of any joint may result in serious deformity. The full extent of this deformity often is not apparent for several years until keloid formation and contraction has resulted in marked limitation of motion, joint changes, dislocation of joints, or ectropion as the case may be. The physician who treats the acute injury is too often heedless of the end-result which he may not be called upon to see.

III. GENERAL CONSIDERATIONS IN TREATMENT OF BURNS

Probably the best first aid treatment for burns is the saline bath which is always available and can be utilized to relieve pain until arrangements for further treatment are made. If the patient is to be treated with tannic acid, oil should never be applied, because this must be removed with ether before the acid is applied and this is a painful process. Morphine should be given at once, the patient should be kept warm, and as soon as possible, fluids should be given. If necessary, they should be given parenterally in order to combat shock and the blood concentration incident to loss of plasma. A subsequent need for fluid must be determined by following the hemoglobin concentration. If the hemoglobin level is high, it indicates a concentration of the blood and, hence, a diminution of blood volume which demands immediate replacement by large quantities of parenteral fluids. It may be necessary to give as much as 7 or 8 liters of saline daily to maintain water balance.

The level of the blood chlorides and urea should also be followed closely, and should the chlorides be diminished, normal saline should be given. The administration of glucose in 10 per cent saline solution intravenously increases the output of urine and is of aid in controlling any elevation of blood urea.

IV. THE TANNIC ACID AND GENTIAN VIOLET TREATMENTS OF BURNS

Since the publication of Davidson's work in the tannic acid treatment of burns in August, 1925, this form of therapy has been widely used in the management of all types and degrees of burns. There is no question but that Davidson is correct in his conclusions⁴ that (1) coagulation of the devitalized tissue by the use of tannic acid lessens toxemia and (2) tannic acid as an initial dressing has an analgesic effect. In addition, the coagulum prevents loss of fluid and chlorides and is of aid in the prevention of the initial shock. Pain is controlled within a few minutes following the first application of tannic acid, and the toxemia of the first week is diminished by the use of this treatment.

The best results are obtained by spraying a freshly made 5 per cent solution of tannic acid directly on the burned area after the blebs have been opened and the necrotic skin trimmed away. This should be repeated every half hour until a firm coagulum is formed.

Spraying with a 1 per cent solution of gentian violet, as advocated by Aldrich,¹ has a similar action and likewise results in the prompt formation of a protective eschar. An ordinary nose and throat "atomizer" spray is an efficient instrument with which to apply the solution. Working on the theory that the cause of toxemia in burns was a bacterial toxin, Aldrich made cultures from a number of burns and found the streptococcus to be the predominant organism. Gentian violet was chosen in preference to tannic acid because of its coagulant and analgesic effects and its specific bactericidal powers against the gram-positive cocci. In addition to this, it is claimed that gentian violet is less destructive to the small islands of epithelium that persist in burned areas and hence epithelization occurs faster than with tannic acid.

Both tannic acid and gentian violet have antiseptic properties and either, when applied to a second-degree burn, will result in an eschar which will be dry and free from infection. But neither of these agents is capable of preventing the

ultimate development of pockets of pus beneath the eschar in areas of a third-degree burn. Gentian violet has the advantage of being stable in solution and hence can be kept on hand indefinitely, whereas tannic acid in solution deteriorates rapidly and must be made up freshly twice a week. Gentian violet stains the bed clothing and everything with which it come in contact and is hence somewhat inconvenient to handle. Tannic acid, on the other hand, leaves no stain when the eschar is dried. In our experience, there is little choice between the two methods of treatment.

In either the tannic acid or the gentian violet method of treatment of third-degree burns, the temperature becomes septic at the end of the first week and pockets of pus begin to form beneath the crusts. If the crusts are not removed and if the infection is not adequately treated, there ensues serious damage to the islands of epithelium which are so essential to prompt epithelization. For this reason, we have followed the method advocated by Glover,² in which the crusts are soaked off in Dakin's solution at the end of the first week. A rise of temperature usually follows moistening of the eschars, but this soon subsides and is never serious. All necrotic tissue should be removed and adequate drainage of all pockets of pus obtained. Hypertonic saline solution (5 per cent) soaks are of great value in cleaning up the infection after the crusts are removed.

V. TREATMENT OF BURNS WITH SALINE SOAKS

The constant application of moist saline packs supplemented by hypertonic saline baths, as advocated by Blair, Brown, and Hamm,⁵ has great value from the standpoint of promoting rapid healing with a minimum of infection and scarring. Crusts do not form, necrotic tissue is debrided as indicated, and infection and coagulation do not destroy the islands of epithelium that remain. Hence, the wound is clean and healthy, and in several weeks, skin grafting, preferably by means of a split thickness (thick Thiersch) graft can be done if necessary. All cases in which there is an extensive burn

on the face, neck, hands, axillae, or over a joint should have early skin grafts to avoid the contracted scars that follow when the wound is allowed to granulate in and epithelize spontaneously over long periods of time.

As soon as the patient is admitted, if it is decided to treat him by means of saline baths, he should be given morphine, placed in a padded tub filled with normal saline and the clothes and dirt soaked from the burns. Relief from pain will occur within five minutes. If necessary, the patient can be left in the tub throughout the treatment, but as a rule, after an hour or two he can be moved to his bed and the burns covered with perforated cellophan over which normal saline packs are placed. The burned area should be kept warm by electric lights under a cradle. Once or twice a day the patient is moved to the tub which is filled with hypertonic (2 to 5 per cent) saline, and here all crusts and necrotic tissue are soaked off or debrided. The tub should be clean but need not be sterile. If the dressings have any tendency to stick to the wound they may be removed painlessly after soaking in the tub.

Although this method of treatment is ideal for obtaining the best cosmetic and functional end-results, it is obvious that it requires much more equipment and nursing care than the methods which use coagulating substances. In addition, there is more handling of the patient and hence as a rule, more discomfort. For the latter reasons, it is probably best to reserve this method of treatment for those cases in which the important issue is not the preservation of life but the preservation of function. It is our opinion that as compared to the saline method, the tannic acid treatment affords greater comfort and as much safety from the standpoint of mortality but does not obtain as prompt or as satisfactory healing. Saline soaks are of especial advantage in burns of the hands, axillae, neck, face, and over the joints.

SUMMARY

1. The treatment of shock, the alleviation of pain, and the regulation of water balance and chloride metabolism are the first considerations in the treatment of burns.

2. Deformities from contractures of scars are frequent and permanently disabling complications of burns.

3. The tannic acid and gentian violet treatment is recommended in cases of severe burns when life is threatened.

4. With the tannic acid and gentian violet treatment, infection occurs beneath the eschars, islets of epithelium are destroyed, and healing is not so prompt or satisfactory as in the saline soak method.

5. Early skin grafts should be applied following the saline soak treatment in third-degree burns involving the face, neck, axillae, hands, or surfaces of joints, where contractures may result in permanent deformity.

ENDOCRINE THERAPY OF BENIGN PROSTATIC HYPERTROPHY

WILLIAM E. LOWER AND D. ROY McCULLAGH

OUR researches during the past seven years have clearly demonstrated that prostatic hypertrophy in experimental animals may result from endocrine imbalance. Recently, we have shown that this hypertrophy can be controlled by the use of a testicular hormone.

The basis for our belief that this treatment might be efficacious is briefly as follows: there is considerable evidence to indicate that the testes, like their analogues the ovaries, produce more than one internal secretion. Gallagher and Koch¹ made concentrates of bull testes and studied the properties of a substance which has since been isolated by Laqueur² and is now known as testosterone. This substance is almost identical in physiological properties with androsterone, which has been isolated from urine by Butenandt.³ Urinary extracts called "androtin," which contain large quantities of androsterone, have been used by us in clinical and laboratory experiments, and it is now clear that the presence of an excess of this substance will cause prostatic hypertrophy in normal animals. This observation is not surprising, since it has been known for many years that castration of man or animals will cause a marked reduction in the size of the prostate gland. This method of treatment is still employed by veterinarians in the control of benign prostatic hypertrophy in animals. Thus, it seems possible that the etiology of this disease might be related to testosterone production and that the control of the amount of this substance elaborated by the testes would be a possible mode of treatment of benign prostatic hypertrophy.

The production of testosterone by the interstitial elements of the testes is under the control of the gonadotropic hormones elaborated in the anterior lobe of the pituitary gland. We have demonstrated that excess stimulation of the interstitial cells by the gonadotropic substances will result in prostatic hypertrophy and that removal of the gonadotropic hormones by hypophysectomy will cause the testes and hence the prostate to cease functioning and become atrophic.

Numerous experiments^{4, 5} indicate that there is an automatic mechanism which normally controls the amount of gonadotropic substance formed and thus maintains the normal level of testicular activity. It appears that a second testicular hormone is produced by the germinal epithelium or some structure closely allied to the tubular portion of the testes. This hormone has been called "inhibin" and is thought to have the property of exerting a controlling influence over the pituitary gland. In the absence of this hormone, the gonadotropic functions of the anterior lobe of the pituitary gland become exaggerated. If the interstitial cells of the testes are still able to function, this could result in prostatic enlargement. Precisely this type of thing might be expected to occur during the involutionary period of a man's life when it is well known that spermatogenesis is retarded and tubular degeneration frequently occurs.

Myers, Vidgoff and Hunter⁶ made an observation which indicates that inhibin is not destroyed in the digestive tract and is active when administered orally. They found that desiccated testicular material, when administered to adult male rats, caused prostatic atrophy. We repeated their experiments and confirmed their results. Unfortunately, however, subsequent attempts to repeat this same experiment have not been successful. Nevertheless, after feeding many rats desiccated testicular material in enormous doses for months, we have noticed no effect on the rat other than the atrophy of the prostate in some cases. It was therefore decided to test the effect of feeding small quantities of testicular material to patients suffering from benign prostatic hypertrophy.

Our clinical experiments have been in progress for fifteen months and a group of 76 selected patients has been treated. All of these individuals had definite signs of obstruction such as hesitancy, slowing of the urinary stream, nocturia and frequency. Before treatment was commenced, the patients were completely studied from the point of view of kidney function and endocrine activity. Many patients were hospitalized and their examination usually included complete studies of the blood chemistry, a kidney functional test, a Friedman test, androtestin assay, the basal metabolic rate, cystoscopic examination, intravenous urograms and in many cases, air cystograms for roentgen visualization of the size of the prostate.

These patients were not obviously suffering from endocrine imbalance but there were certain findings which led us to believe that the majority did not possess a normal endocrine system. The basal metabolic rate was almost uniformly low although there were no definite signs of hypothyroidism. According to our theory of benign prostatic hypertrophy, one might expect to find some pituitary involvement. Dr. Perry McCullagh and Mr. Kenneth Cuyler are studying this problem and their unreported findings show that in some cases of prostatic hypertrophy, there may be so much pituitary-like hormone in the urine that a positive Friedman test may be observed which is similar to that obtained in pregnancy.

The majority of the patients treated were not those who had suffered from long-standing obstruction with marked renal impairment as indicated by the intravenous urograms, blood urea and kidney functional tests, which in most cases were normal. Their average age was sixty-eight and one-tenth years, the youngest of the group was fifty-four and the oldest seventy-seven years of age.

All types of hypertrophy were included although we felt that the soft, adenomatous hypertrophies should respond best, and therefore this type of case has been favored in selecting those for treatment.

Case I.—The patient was a man, sixty-six years of age, who came to the clinic complaining of complete urinary retention. Two or three years before

this examination, difficulty in urination had begun which resulted in complete retention of five days' duration.

On cystoscopic examination, the bladder neck showed rather pronounced bilateral lobe intrusion and no median lobe was present. The prostatic urethra was markedly lengthened and the lateral lobes met in the midline throughout this distance. Rectal examination revealed the prostate to be quite large but fairly firm.

Laboratory examination revealed the blood urea to be 48 mg. per 100 cc., and in view of the poor kidney function and nitrogen retention, it was decided to use medical treatment.

The patient entered the hospital and to care for the complete urinary retention, he was catheterized twice or three times daily. The capsules were

g. 186.—Chart showing change in urinary symptoms in Case I following treatment with inhibin.

ministered and for three weeks no improvement could be noticed. The patient then found that he was able to void a little between catheterizations and his improvement continued until five weeks after inhibin was started, when he was able to empty his bladder completely. He was discharged from the hospital and at that time, the blood urea had returned to a practically normal level and he felt generally much stronger and better. Figure 186 shows this patient's progress in regard to the ounces of residual urine, diurnal frequency, and nocturia.

This patient now feels so well that he considers himself cured; he voids easily and has nocturia only once nightly.

Case II.—This patient was a man, fifty-five years of age, who came to the clinic complaining of practically complete urinary retention. A very small amount of urine could be passed and catheterization was necessary twice daily. These symptoms began seven years before our examination and several months before admission, nocturia had become a distressing symptom, occurring every fifteen or thirty minutes.

Physical examination revealed no abnormalities except for the prostate which was markedly enlarged, smooth and of moderate consistency. Cystoscopic examination revealed an obstructive type of bladder and trilobar hypertrophy of the prostate gland with pronounced extravescical bilateral lobe enlargement.

This type of enlargement is that for which prostatectomy would be recommended but also the type in which one might expect satisfactory results after endocrine therapy. This latter method was accepted by the patient and treatment was begun. After ten days, the patient was able to void so well that

Fig. 187.—Chart showing change in urinary symptoms in Case II following treatment with inhibin.

catheterization was discontinued and three days later, only 55 cc. of residual urine were present when he was discharged from the hospital. Figure 187 shows the progress which this patient made.

This patient has been able to return to his work, is able to urinate almost normally and catheterization yields only a few cubic centimeters of residual urine. Nocturia occurs only once at most and occasionally it is entirely absent.

Case III.—The patient was a physician, fifty-seven years of age, who came to the clinic with complete urinary retention which had been present for two days and for which he had resorted to self-catheterization. Symptoms of ob-

struction had begun three or four years before our examination and nocturia from eight to twelve times had been present for the previous six years.

Physical examination revealed trilobar hypertrophy of the prostate of a smooth, soft type; otherwise, the general physical condition was good.

The patient entered the hospital for treatment with inhibin which was administered three times daily. Intermittent and rather frequent catheterization was necessary during the first few days but after seven days, he was able to void so well that catheterization was discontinued and at the time of his discharge from the hospital five days later, he was able to empty his bladder completely (Fig. 188).

When we last saw this patient, he considered himself absolutely well. He was able to void freely and easily with no

Fig. 188.—Chart showing change in urinary symptoms in Case III following treatment with inhibin.

hesitancy whatever. The voided urine was clear and catheterization yielded no residual urine.

Figure 189 shows another case in which the patient was admitted with complete urinary retention. Treatment with inhibin was begun and nocturia and diurnal frequency were greatly lessened and no residual urine was present after five weeks.

Of necessity, the dose has been empirical since no method of quantitative assay has as yet been developed. For the same reason, it has been impossible to make inhibin concentrates,

or to know how much active material each patient was receiving. Fresh beef testicular material was desiccated in vacuo at 60° C., pulverized and placed in gelatin capsules. Each patient received the equivalent of 60 Gm. of testes daily. This treatment was usually continued for a period of three months. None of the patients received any other type of treatment except in cases of complete retention when the patient was catheterized regularly or an indwelling catheter was used for a time until the patient could void. In the other patients, cath-

Fig. 189.—Chart showing change in urinary symptoms following treatment with inhibin.

eterization was done only at regular intervals of from five to fifteen days in order that any change in the amount of residual urine might be noted.

In the patients who reacted favorably, the first signs of improvement were usually noted less than two weeks after the beginning of treatment, and maximum improvement was obtained in less than two months. These signs of improvement were decreased nocturia, greater ease in voiding, increase in the size of the stream and reduction in frequency. All patients reported a feeling of general well being.

Of the 76 patients who have been included in this experiment, 48 or 63.1 per cent have had definite improvement in symptoms. As shown in the table, improvement has been observed in numerous types of benign hypertrophy.

The longest duration of symptoms in the improved patients was 2.01 years and in the unimproved patients, 5.1 years.

The reason why 36.1 per cent of the patients did not react favorably to this treatment is not known. It has been stated that 20 per cent of the cases which are diagnosed clinically as benign prostatic hypertrophy are subsequently shown to be malignant. This, no doubt, accounted for some of the failures. One would scarcely expect satisfactory results if the gland has become very fibrotic or if bladder pathology such

Improved and free from symptoms.	14	17	4	13
Unimproved.	10	9	4	5
Total.	24	26	8	18

as marked atonicity or diverticula was present. We have observed failures in treatment following punch operation and cystotomy where there was a sclerotic type of middle lobe and in a case with very atonic and distended bladder and associated diabetes. Possibly greater success will result from this type of treatment when more concentrated preparations of inhibin are available.

The exact mechanism by means of which the improvement in symptoms has been obtained also remains obscure. In our clinical cases, we have no physical or laboratory proof that the prostate has undergone any atrophic changes such as have been observed in experimental animals. These may become more apparent if the dosage is increased or the treatment is

more prolonged. It may be that this group represents a percentage of patients who would improve under ordinary conditions without medication but if this be true, then we have been operating upon too many patients with this type of prostatic hypertrophy. Whether or not this is true can only be settled by more extensive investigation.

CONCLUSIONS

Laboratory investigations indicated that benign prostatic hypertrophy might possibly be due to a disturbance of normal physiology. Our knowledge concerning the endocrine influences on prostatic activity indicated that the imbalance might be the result of the failure of the testes to produce adequate quantities of inhibin. Seventy-six cases of benign prostatic hypertrophy have been treated with a testicular preparation and in 63.1 per cent they have been relieved of the symptoms for which they sought medical aid.

THE SYMPTOMS, DIAGNOSIS, AND TREATMENT OF CYSTITIS

C. C. HIGGINS

THE triad of symptoms usually manifested by a patient with cystitis are frequency of urination, pain and pyuria.

SYMPTOMS

Frequency of Urination.—As a general rule, the patient's attention is directed to the inflammatory process by varying degrees of urinary frequency. Since frequency is a constant symptom, it is likewise an expression of the severity of the disease. In the acute cases, the patient may be required to empty the bladder every fifteen or twenty minutes during the day and night, while in the more mild or chronic cases, the desire to void occurs every two or three hours during the day and two or three times during the night. Urgency and a constant desire to void which is accompanied by considerable discomfort and tenesmus may be pronounced.

Pain.—Pain occurs to a varying degree, dependent upon the acuteness of the cystitis. In the presence of retention of urine, more or less constant pain may be felt over the bladder. However, as a general rule, the pain is more severe during the act of urination or it may be terminal in type. In the presence of acute cystitis, severe pain and tenesmus is experienced at the completion of urination, this being aggravated by the patient's straining after the act of urination. The distress is frequently noted in the perineal or over the suprapubic region.

Pyuria.—Pyuria may be noted by the patient. The urine may be only faintly cloudy or quite turbid in appearance. In the presence of acute cystitis, the urine may likewise be

tinged with blood and occasionally the bleeding may be quite profuse, suggesting the presence of a vesical neoplasm. However, more frequently a few drops of occult blood may be passed at the end of urination.

In severe cases, general symptoms may also be present such as fever, chills, loss of appetite, nausea, and at times vomiting. The symptoms of chronic cystitis simulate those of the acute process, but are much more mild and less pronounced.

DIAGNOSIS

The clinical diagnosis of cystitis is usually determined by a history of frequency, pain and the presence of pyuria. Oftentimes however, the inflammatory lesion in the bladder is associated with inflammatory lesions of the kidney or other parts of the genito-urinary tract. In such cases, conservative treatment alone fails to alleviate the patient's symptoms, and failure to discover the renal condition may lead to loss of renal function and progressive invasion of the kidney by the inflammatory process with ultimate destruction of the renal tissue.

Therefore, in cases in which the patient's symptoms do not subside within a period of ten days or two weeks following adequate treatment, cystoscopic examination, catheterization of the ureters, and the making of pyelograms, if deemed advisable, are indicated. In cases in which conservative treatment is employed, a specimen of urine secured by catheterization should be examined. In women it is quite important to secure such a specimen as a vaginal discharge or blood due to the menses may cause erroneous conclusions to be drawn. In men, the voided specimen secured by catheterization should be collected in 2 or 3 glasses. In the voided specimen, if the urine in the first glass is cloudy and that in the second and third glasses is clear, the cloudiness and turbidity of the urine in the first glass is due to the presence of pus and debris in the urethra. If the urine in both the second and third glasses is hazy, an infection exists in the bladder. Thus, it can be seen that if only one specimen were collected and the urine was cloudy, the presence of bacteria and pus would lead to an

erroneous diagnosis of cystitis, whereas in reality, the inflammatory process might be confined to the urethra. Likewise, routine examination of the urine should be made for the specific gravity, the presence of albumin, sugar, pus, bacteria, blood casts and crystals. As a general rule, the colon bacillus, tubercle bacillus, and gonococcus are found in urine with an acid reaction, while streptococcus, staphylococcus, proteus, and all urea-splitting organisms are found in an alkaline urine. Usually, the infecting organism is found to be the colon bacillus or staphylococcus. If media are available, culture of the urine in glucose brain broth and blood agar is advisable.

Slides are made of three specimens for examination of the sediment:

1. One for routine examination for pus, casts, red blood cells, and crystals. This should be a wet preparation.
2. One is stained by Gram's method for the study of the organisms present.
3. One is stained by the Ziehl-Neelson method for determination of the presence of tubercle bacilli.

Likewise, if a drop of pus can be expressed from the urethra, a Gram stain should be made and carefully examined for intracellular diplococci.

As stated previously, these investigations suffice for the routine study of a patient with cystitis. If, however, no improvement follows treatment, cystoscopic examination is advisable. By this procedure, one is able to determine whether the bladder is being emptied completely, whether an obstructive lesion is present in the urethra or bladder neck, or whether the retention is associated with lues or a tumor of the spinal cord. After inspection of the bladder, a specimen of urine is collected from each kidney for complete study, and pyelograms may be done if advisable.

DIFFERENTIAL DIAGNOSIS

As the symptoms of frequency, pain and pyuria are not pathognomonic for cystitis *per se*, but also are symptoms associated with other inflammatory lesions of the genito-urinary

tract, careful interpretation of the findings is essential. Cystitis must be differentiated from pyelitis, pyelonephritis, renal tuberculosis, calculi, pyonephrosis, Hunner's ulcer of the bladder, diverticula of the bladder and urethritis. By cystoscopic examination, ureteral catheterization, and roentgenographic study, the presence of a renal infection can be detected and the presence of such lesions as calculi, tuberculosis, or pyonephrosis can be discovered or ruled out.

Careful inspection and palpation of the urethra as a general rule will suffice to determine the presence of urethritis, polyps or a caruncle, although in certain cases, urethroscopic examination may be necessary. Vaginal examination will reveal the presence of a cystocele, or a thickened ureter due to tuberculosis may be felt. It is always advisable to make a speculum examination of the cervix to determine the presence of erosions and endocervicitis.

In men, palpation of the prostate and seminal vesicles will reveal an enlarged, tender, tense prostate or distended vesicles if the inflammatory lesion involves these structures. Likewise, a history of gonorrhea or instrumentation may be elicited. Pathological lesions in the bladder such as calculi, Hunner's ulcer, trigonitis or diverticuli are ruled out by cystoscopic examination. In uncomplicated cases of Hunner's ulcer of the bladder, the characteristic differentiating symptoms are the marked frequency, both day and night, which Furniss¹ has very aptly described as clocklike in its regularity, and there may be marked dysuria while the urine is clear and sparkling, unless a coexistent infection is present.

Bacteriuria is differentiated by microscopic examination of the urine. In the presence of this condition, numerous organisms may be present in the urine which is free from pus.

If any doubt exists regarding the differential diagnosis due to the fact that so many inflammatory lesions of the genitourinary tract may simulate cystitis, cystoscopic examination should be employed.

TREATMENT

The treatment of uncomplicated cases of cystitis consists of (1) general measures, (2) internal medication, and (3) local treatment.

In acute cases, rest in bed is essential. A simple diet is prescribed and meats such as beef, pork, ham, and bacon, which contain a considerable amount of extractives, are avoided. Small portions of chicken, veal and fish are permissible. Pepper, salt, mustard, catsup, all condiments and spices should be avoided, as should tea, coffee, liquors and all alcoholic beverages. The patient should drink an abundance of water and milk, at least one glassful every hour being taken.

The bowels should be regulated by the use of mild laxatives. The application of heat by means of an electric pad or hot water bottle to the suprapubic and perineal region relieves the discomfort of the patient.

The medical treatment should seek (1) to alleviate the patient's pain and discomfort and (2) to eradicate the infection. Anodynes should be employed to relieve the discomfort of vesical spasm and the use of codeine internally, or of triple bromides may suffice. Relief may also be afforded by opium and belladonna suppositories which are made of $\frac{1}{2}$ grain of powdered opium and $\frac{1}{4}$ grain of extract of belladonna. Likewise, the administration of alkalies may give considerable relief from discomfort. We have found the following prescriptions beneficial:

		Gm. vel cc
R	Sodium bromide.....	30
	Tincture hyoscyamus.....	45
	Elixir simplex.....	q. s. ad 180
Sig. One teaspoonful in a glass of water after meals.		

		Gm. vel cc.
R	Tincture belladonna.....	10
	Potassium citrate.....	30
	Aqua destillata.....	q. s. ad 120
Sig. One teaspoonful in water after meals.		

R	Gm. vel cc.
Potassium acetate.....	30
Tincture hyoscyamus.....	30
Water.....	q. s. ad 180

Sig. Two teaspoonfuls in a little water after meals.

R	Gm. vel cc.
Ext. fld. hyoscyamus.....	10
Liquor potassium or potassium citrate ..	12
Syrup acaciae.....	q. s. ad 120

Sig. One teaspoonful every four hours.

The urinary antiseptic which has been most satisfactory in our hands is urotropin and in cases of colon bacillus or staphylococcus cystitis, it seems preferable to other antiseptics. For this treatment to be efficacious, the reaction of the urine must be acid and this can be accomplished by the administration of from 40 to 80 grains of sodium acid phosphate and urotropin daily and in some cases, larger doses are required to render the urine acid. There is a tendency to administer insufficient amounts of urotropin and sodium acid phosphate and in some cases, 60 to 70 grains a day are required to secure satisfactory results. Likewise, in infections due to the urea-splitting organisms, sodium acid phosphate and urotropin are beneficial. Methylene blue may be administered also in doses of from 1 to 2 grains three times daily, but this has not given as good results. The use of capsules of oil of sandalwood has been satisfactory in cases of cystitis associated with gonorrhea. Pyridium (2 tablets of 0.1 Gm. each, three times a day) is also helpful.

Finally, in the very irritable bladder, we have found that hexylresorcinol, 1 capsule (0.15 Gm.) four times daily or even in larger doses, may give considerable relief.

Local Treatment.—During the very acute stage of the disease, we prefer to rely upon medical and palliative treatment as irrigations accompanied by distention of the bladder cause considerable pain. If, however, local treatment seems necessary, instillations of 25 per cent protargol or 16 per cent gomenol suffices. We have found that gomenol is more satis-

factory in relieving the patient's pain. In the subacute or chronic stages, irrigations, a solution of 1:4000 potassium permanganate or 2 to 3 per cent boric acid solution may be used followed by the instillation of argyrol, protargol or gomenol. Irrigations are made daily during the subacute stage and then twice weekly. If ulceration of the bladder is present, topical applications of 10 or 15 per cent silver nitrate solution is helpful. Finally, the ketogenic diet may be employed, especially if a coexisting renal infection is present.

CONCLUSIONS

All patients with cystitis which does not respond to the usual conservative treatment in a period of ten days or two weeks should have cystoscopic examination and complete urological investigation. Complete comfort can be afforded during the acute stage by anodynes and internal medication.

Uncomplicated cases of cystitis respond to conservative, hygienic, dietary, local and medical therapy.

THE DIAGNOSIS OF THE BLOOD DYSCRASIAS IN CHILDREN

RUSSELL L. HADEN

WITH a few exceptions, the blood dyscrasias of the child do not differ greatly from those of the adult. A few diseases such as pernicious anemia seen commonly in the adult occur seldom, if ever, in the child. On the other hand, erythroblastic anemia occurs only in infancy and early childhood, and certain dyscrasias such as true hemophilia occur principally in young individuals. Both the hematological and clinical manifestations of the blood dyscrasias are often exaggerated and variable in youth since the hematopoietic system of the growing child is more unstable and thus more responsive to stimuli than that of the fully grown adult. For this reason, immature forms of both red and white cells appear more frequently in the circulating blood of the child than the adult, so the occurrence of abnormal cells in the child may not have the same significance as in the adult.

In every patient suffering from a blood dyscrasia, we must consider (1) the tissues in which the cells are formed—normally, bone marrow and the lymph nodes, and abnormally, the spleen and other tissues; (2) the tissues in which the cells are destroyed, principally the spleen and other parts of the reticulo-endothelial system; and (3) the circulating blood elements which represent a balance between blood formation and blood destruction. The important dyscrasias are best discussed under three heads:

1. Those involving primarily the red cells.
2. Those involving primarily the white cells.
3. Those involving primarily the platelets and other coagulating elements.

I. BLOOD DYSCRASIAS INVOLVING PRIMARILY THE RED CELLS

The dyscrasias involving the erythrocytes concern almost entirely the anemias, since polycythemia vera is exceedingly rare in childhood. There are also fewer causes to consider for the anemias in childhood than in the adult although in general, the same etiologic factors must be considered. The following classification is a convenient one to follow in all anemias. This classification emphasizes that the examination of the circulating blood reveals only the balance between blood loss and blood regeneration at the time the count is made. It follows that every anemia is due to increased blood loss, decreased blood formation or a combination of these two factors. The rate of formation is best measured by the reticulocyte count, since this indicates the number of young cells delivered to the circulation and the rate of blood destruction by the amount of bile pigment formed, since this is the end-product of hemoglobin destruction. Unfortunately, the bile pigment formed cannot be measured easily in the bile or as urobilin in the stools, but if there is excessive pigment formation, it accumulates quickly in the blood plasma and can be measured in terms of the icterus index or van den Bergh reaction.

CLINICAL CLASSIFICATION OF ANEMIA

I. Due to increased blood loss:

1. Acute hemorrhage.
2. Accelerated destruction of red cells.
 - (a) By toxic factors especially infection.
 - (b) By rapid removal from blood stream in the spleen because the cell is abnormal in shape or size.
 - (1) Hemolytic jaundice.
 - (2) Sickle-cell anemia.
 - (3) Erythroblastic anemia.

II. Due to decreased blood formation:

1. Quantitative decrease in functioning marrow by aplasia due principally to infections, poisons, or replacement of erythrogenic tissue by overgrowth of myeloid tissue as in leukemia.
2. Quantitative decrease in activity of marrow present especially by infection and other toxemias, cachexia and malignancy.

3. Qualitative decrease in marrow function due to a lack of specific elements necessary for normal red cell formation.

(a) Deficiency in iron due to:

(1) Insufficient food intake or supply by mother during fetal life.

(2) Chronic hemorrhage.

(b) Deficiency in the erythrocyte maturing factor (EMF).

These different classes and causes of anemia may be considered in greater detail. Anemia due to acute hemorrhage in childhood is uncommon but may be caused by trauma or be secondary to a defect in blood coagulation. Rarely there is chronic gastro-intestinal hemorrhage as from an ulcer in a Meckel's diverticulum. The cause of a hemorrhagic anemia is usually apparent. The cells remaining in the circulation are normal in shape, size and hemoglobin content, so the color and volume index is normal as well as the icterus index. Regeneration starts rapidly to replace the lost cells so the reticulocyte count should rise soon after the hemorrhage.

The hemolytic anemias are most interesting. It is especially common for infections to cause increased hemolysis of red cells and so produce a hemolytic anemia. Unless the marrow is depressed at the same time, there is usually a quick response of the marrow to the need for new cells with an outpouring of cells and therefore a rise in the reticulocyte count occurs. If many cells are destroyed, the spleen has more work to do and thus becomes enlarged if the blood destruction continues sufficiently long. With the excessive destruction of hemoglobin, bile pigment is formed beyond the capacity of the liver to excrete it, and the icteric index rises. The cells in the circulation in a hemolytic anemia due to infection are normal.

Congenital hemolytic jaundice, sickle-cell anemia and erythroblastic anemia are all examples of hemolytic anemias in which there is a congenital defect in shape or character of the red cell. Since the cells are abnormal, they are quickly taken out of circulation by the spleen so there is splenic enlargement and a rise in the bile pigment of the plasma. The bone marrow is overactive in trying to compensate for the

excessive destruction, and the reticulocyte count is high due to the many new cells in the circulation. In congenital hemolytic jaundice, the cells tend to be a spheroid rather than a biconcave disk. This should be designated, as suggested by Naegeli,¹ as spherocytic anemia. In sickle-cell anemia, the same conditions hold due to the sickle-shape of the red cells. The characteristic finding in erythroblastic anemia, so designated by Cooley,² is the enormous number of erythroblasts in the circulating blood. These are also taken out by the spleen, so the characteristic chain of events in a hemolytic anemia occurs here also. The clinical manifestations in hemolytic jaundice are anemia, jaundice with normal-colored stools, and an enlarged spleen. In sickle-cell and erythroblastic anemia, the anemia and splenic enlargement are the presenting clinical findings.

In the anemias due to decreased blood formation, less hemoglobin is destroyed, so jaundice does not occur. The icterus index is usually lower than normal and the reticulocyte count is low due to the marrow aplasia or replacement. Infections may cause a profound aplasia which usually involves all elements of the marrow so the platelet and leukocyte count are low as well as the red cell count. Other types of cellular toxins, such as arsphenamine, have a similar effect. Leukemic infiltration in the marrow simply crowds out the red-cell forming tissue. Here, the white count and platelet count are usually high except in the leukopenic form of leukemia, when the picture is indistinguishable from aplastic anemia unless qualitative changes such as the appearance of lymphoblasts and immature cells of the myeloid series are found. The red cells in aplasia of the marrow usually show no nucleation or basophilia, and such cells as are present are normal except for a tendency to macrocytosis.

In the anemias due to a quantitative depression, there is decreased activity of the marrow which remains normal in amount. Here, the important causative factors are infection such as in the urinary tract and sinuses, or a general defect in nutrition with consequent failure in supply or utilization of

the substances necessary for blood formation. The rare cases of malignancy in children may produce anemia by depressing the marrow also. Here again, the cells present are relatively normal, the reticulocytes are low and there is no increase in bile pigment formation. Leukocytosis is usually absent. Only the symptoms and signs of anemia form the presenting clinical picture.

The qualitative defects in marrow function in the child concern almost entirely the iron metabolism, as this is the substance most commonly deficient. Here the defect is primarily in hemoglobin synthesis rather than red-cell formation, so the characteristic finding on blood examination is a very low color index. If this continues sufficiently long, the cells become small, and the volume index is low also. The white cells and platelet counts remain normal; the icterus index is less than normal and the reticulocytes are not increased.

An iron deficiency occurs frequently in young infants due to an insufficient iron supply of the mother during pregnancy, or a greater need for iron than can be supplied as in twins. Such an anemia can be produced regularly in experimental animals by giving the mother a diet deficient in iron. If a child is given a diet low in iron, such as an exclusive milk diet for a sufficiently long period, an iron deficiency anemia inevitably develops. A chronic hemorrhagic anemia is primarily an iron deficiency anemia, but this is uncommon in infancy and childhood. There is nothing characteristic clinically about an iron deficiency anemia, although a moderate enlargement of the spleen is not uncommon. It is questionable whether a deficiency in the erythrocyte maturing factor (EMF) ever occurs in childhood.

II. BLOOD DYSCRASIAS INVOLVING PRIMARILY THE WHITE CELLS

Leukemia is not uncommon in childhood. The disease is much more apt to be acute or at least subacute rather than the more common chronic type seen in the adult. The onset is often sudden with fever, enlargement of lymph glands and

spleen, and rapidly progressive anemia. Petechiae, due either to a platelet deficiency or a toxic effect of the disease on the blood vessel walls, are frequent.

The characteristic blood finding in leukemia is a leukocytosis, with the presence of immature cells of either the lymphoid or myeloid series. The immature white cells are often very young, making it difficult to differentiate between lymphoblasts and myeloblasts. From a clinical standpoint this distinction is of little value, so if there is any question about the type, it is best to simply designate it a "blast" leukemia. Typically, there is more enlargement of the lymph glands in the lymphoid leukemia and more enlargement of the spleen in the myeloid type, although such a clinical differentiation often does not check with the blood and histologic findings.

It was formerly thought that most acute leukemias in children were lymphoblastic, but we now know that the myeloblastic type is also common. The oxidase reaction was once depended on to differentiate the two types with the idea that cells of myeloid origin should give a positive reaction. If the reaction was negative, the cells were designated lymphoblasts, but we now know that myeloblasts do not give a positive reaction unless granules have begun to appear, so the oxidase reaction is of no value in differentiating the two forms of young cells. The anemia is just as marked in the two types although the platelet count is more apt to be low in the lymphoid than in the myeloid type.

An outspoken leukemia may be present without significant glandular or splenic enlargement. Here, there is usually fever, petechiae and often necrotic oral lesions. The diagnosis in such cases is, of course, made only by blood examination or sometimes only at autopsy. The great difficulty in such cases is to differentiate leukemia from the blood reaction occurring in certain infections because an infection may so stimulate the bone marrow as to flood the peripheral blood with immature forms in the absence of true leukemia. If the entire clinical and blood picture does not seem to correlate properly, it is best to be guarded in making a diagnosis of leukemia.

Time and further blood examinations will usually make the correct diagnosis.

The clinical condition most frequently confused with leukemia in the child is infectious lymphadenosis (mononucleosis). Here, there is glandular enlargement and often splenic enlargement with a leukocytosis and the appearance of mononuclear cells in the blood which may be mistaken for lymphoblasts or myeloblasts. The patient is seldom ill; however, hemorrhagic and local necrotic features are absent, and a careful study of the mononuclear cells shows that they are not young forms but simply abnormal forms to find in the circulating blood.

Most difficult diagnostic problems in leukemia are seen in children with a leukopenia. Such cases are not uncommon. Usually, the anemia or the enlargement of glands or spleen is the presenting clinical symptom. The anemia is often extreme, and the leukocyte count may be as low as 1000 with a high percentage of mononuclear cells. If the child does have leukemia, a careful search, especially with concentration specimens, will usually show immature forms characteristic of leukemia. An aplastic anemia will give the same clinical picture, but here the immature white cells should be absent. The correct diagnosis may be impossible, however, until it is made at autopsy.

Agranulocytosis is rare in the child but it may occur. It is the opinion now that most primary cases in the adult are due to some drug such as amidopyrine, which acts as a toxic agent on the marrow, preventing the normal development and delivery of leukocytes. Infection may act similarly.

III. THE BLOOD DYSCRASIAS INVOLVING PRIMARILY THE PLATELETS AND OTHER COAGULATING ELEMENTS

Hemorrhage without injury or out of proportion to an injury is necessarily due to a defect in coagulation of the blood or to an increased permeability of the capillary walls. Such a pathologic hemorrhage is not unusual in childhood. The three important primary types of hemorrhagic disease

seen at this age period are: (1) hemorrhage of the newborn; (2) true hemophilia; and (3) hemorrhage due to a deficiency in blood platelets or thrombopenia.

Hemorrhage of the newborn occurs only in infants, as the name indicates. It is characterized by spontaneous hemorrhage, usually not later than the second week of life. The bleeding may be from the gastro-intestinal tract, from the site of separation of the cord, or into the subcutaneous or subdural tissues. Relatively few careful blood studies have been made in such cases. The platelets are normal, but the coagulation and bleeding times are prolonged due apparently to a prothrombin deficiency. Transfusion usually effects a complete cure. The development of such a hemorrhage is usually prevented by giving whole blood intramuscularly immediately after birth.

True hemophilia is primarily a disease of childhood, since it is a most serious condition and most children so afflicted die from hemorrhage early in life. The diagnosis of hemophilia should be made only in males. There is usually a family history of abnormal bleeding in the male members of the mother's family. In this disease, the abnormal bleeding is due to a prolonged coagulation time and prothrombin time without quantitative decrease in platelets, or abnormality of clot retraction or bleeding time. The fundamental defect seems to be an increased resistance of the platelets to dissolution, so that the thromboplastin is consequently deficient. Clinically in such cases, hemorrhage from the mucous membranes and true petechiae seldom occur. Hemorrhage into the joints occurs practically always and large hemorrhages into the subcutaneous tissues and body cavities are frequent.

The platelets seem easily depressed in childhood, so purpura due to a quantitative deficiency in platelets is common. We speak of this condition as idiopathic thrombopenia, although there must be a cause for the platelet depression. The condition usually develops acutely with petechiae and bleeding from the mucous membranes, especially from the nose. There is seldom bleeding into joint spaces or body cavities. Often

there is a history of a preceding infection such as one of the acute exanthemata, tonsillitis or pyelitis. Here the essential blood findings are a decrease in platelets with failure of clot retraction and an increase in bleeding time. Such cases are usually self-limited and can be tided over by transfusion. If the thrombopenia and purpura become chronic, only splenectomy will give relief.

Hemorrhagic disease may also develop secondarily in children, especially the type due to a platelet deficiency such as occurs with aplastic anemia and leukemia, or may occur in the course of some other manifest disease. Likewise, there may be a defect in the clotting mechanism with consequent abnormal bleeding as the result of jaundice or of a deficiency in fibrinogen from liver disease.

SUMMARY

The blood dyscrasias of the child do not differ greatly from the dyscrasias of adult life. The blood making and destroying mechanism is more labile in youth, so the response to a given stimulus on the part of the bone marrow, spleen and other parts of the reticulo-endothelial system is apt to be more exaggerated in the growing child. For this reason, greater judgment must be exercised in drawing conclusions from both clinical and laboratory data in the child than in the adult. The dyscrasias are more apt to be acute at this period of life. The diagnostic criteria for establishing a diagnosis of some blood dyscrasias are essentially the same in all age periods.

THE TRANSFUSION OF BLOOD IN GENERAL MEDICAL PRACTICE

RUSSELL L. HADEN

I. INDICATIONS

THE transfusion of blood is one of the most valuable of all remedial measures employed in general medicine. Every body activity depends on an adequate supply of oxygen and of fluid and food which are furnished only by the blood. Transfused blood supplies the fluid volume necessary for adequate circulation, erythrocytes containing hemoglobin to transport oxygen, protein needed to maintain the proper osmotic pressure within the vessels, platelets and other substances to aid blood coagulation, and antibodies to resist infection, and at the same time, stimulates the bone marrow to greater activity.

In acute hemorrhage, the indication for transfusion is generally absolute. Here, the rapidly reduced volume of blood is usually the most serious phase of the hemorrhage. If as much as one third of the circulating blood is quickly lost, exitus ordinarily follows, since the heart cannot maintain the circulation on the reduced blood volume. In most instances, the hemorrhage is accompanied also by an element of shock. In acute hemorrhage of any magnitude, even without shock, or in a small hemorrhage with shock, transfusion should always be done. The results are usually most brilliant and often life-saving.

In chronic hemorrhage the fluid lost is replaced, so that the total blood volume is returned to normal. Here, the most important element is the anemia. We now know that this type of anemia is primarily an iron deficiency anemia, since this is the one building stone needed for red cell and hemoglobin

formation with a very small reserve supply. As a rule, there is little reduction in the number of cells, but a marked reduction in hemoglobin and consequently a low color index. If the hemoglobin is reduced a sufficient amount and for a sufficient length of time, microcytosis of the red cells develops and consequently the volume index is low.

In uncomplicated chronic hemorrhagic anemia, the administration of large doses of iron such as 60 to 90 grains of Bland's pills daily, will lead to a rapid synthesis of hemoglobin and return of the blood to normal. Such a procedure takes time, however, and often it is more economical for the patient, especially if confined to a hospital, to be transfused, although the iron should be given also to build up the body reserve. In some cases of chronic hemorrhagic anemia, other factors are present which prevent or interfere with the normal formation of hemoglobin, so the expected response to iron therapy of a daily increase in hemoglobin of 1 per cent is not obtained. Here, transfusion may be of great help in stimulating the marrow.

In other cases, an iron deficiency anemia may result from a deficient food supply of iron as on an exclusive milk diet. Not infrequently, there is a defect in absorption or utilization (idiopathic hypochromic anemia) of iron even with an adequate intake. Here also, the response to iron therapy in massive doses is most gratifying and transfusion is seldom necessary unless a rapid return to normal is indicated as in preparation for an operation or to combat other complications such as infection.

In pernicious anemia, transfusion was the mainstay of treatment before the development of liver therapy. We now know that this type of anemia is due to a deficiency in the erythrocyte maturing factor (EMF) formed by the interaction of an intrinsic factor secreted by the stomach on an extrinsic factor supplied by the food. This factor is necessary for the normal growth of the red cell just as iron is necessary for the normal synthesis of hemoglobin. The supply of this factor to the marrow may be altered by liver disease since the liver

is the normal storage depot, or by diarrhea, which prevents absorption.

Since pernicious anemia is a deficiency disease, the therapeutic indication is to supply the missing factor in amounts adequate for the maintenance of a normal blood count for the life of the patient. If the anemia is extreme and is progressing rapidly, transfusion should always be done to tide the patient over the several days that are required before an appreciable effect from liver therapy is secured, even when given parenterally. It is the consensus of opinion, however, that transfusion is of no advantage in the management of the disease except as an emergency measure when the cell count is very low or in the presence of some complicating factor.

In the anemia of pregnancy, transfusion has been found of the greatest value. This anemia is probably a deficiency anemia incident to the pregnant state, so it is self-limited and is cured by restoring the supply of material needed for red cell and hemoglobin formation. The same result is attained, although more slowly, by giving an adequate diet together with iron and liver extract.

In most of the other anemias due to factors which cannot be removed such as chronic nephritis, inoperable malignancy, certain infections, or in such conditions as leukemia, sickle-cell anemia or idiopathic aplastic anemia, transfusion is purely palliative, but is most valuable, since the transfused cells probably live as long as cells made by the patient (two to six weeks) and function normally as oxygen carriers. At the same time, the transfused blood acts as a stimulant to the bone marrow. Even if not curative, transfusion in such cases contributes greatly to the well-being of the patient.

In many toxic conditions, transfusions may be life-saving. In acute poisonings such as by carbon monoxide or bichloride of mercury, the patient may be tided over by the supply of new blood. Transfusion is especially indicated if the bone marrow is involved such as in primary granulopenia (agranulocytosis) which is usually due to the effect of amidopyrine. If the offending drug is withdrawn and the patient tided over,

especially by transfusion, recovery should usually take place. This holds true also for other agents such as arsphenamine or benzol, which injure the bone marrow, but involve predominantly the erythrogenic rather than myeloid tissue, unless the damage to the marrow is beyond repair.

In sepsis with or without anemia, transfusions should always be considered and usually employed. Here as a general rule, there is some decrease in red cells and hemoglobin, and these are replaced by the transfused blood. The bone marrow is depressed in the presence of most infections and is supported and stimulated by new blood. The transfused blood aids in combating the infection by supplying chemical antibodies as well as leukocytes which will function more efficiently than the ones formed in the damaged bone marrow of the patient. Recently, the transfusion of blood from a donor previously subjected to nonspecific protein shock has yielded encouraging results in the treatment of sepsis of different types.

Probably too little attention has been given to supplying blood proteins by transfusion because this is the only method by which they can be supplied if the patient is not making them in adequate amounts. The site of their manufacture in the body is not definitely known, but it is probably the liver; therefore, it is in liver diseases such as advanced cirrhosis that the proteins are not supplied in adequate amounts. If protein is lost through the kidney by proteinuria or into serous cavities as in the abdomen, in the presence of cirrhosis of the liver, or in states of hypermetabolism and excessive intestinal motility such as hyperthyroidism, the blood level is below the optimum level. The only way in which the blood proteins can be elevated quickly is by transfusion, although dehydration increases the concentration without increasing the total amount in the circulation.

In pathologic hemorrhage, there is usually some defect in the mechanism of blood coagulation. The deficiency may be in platelets or in the coagulating ferments. Here again, the only way to quickly destore the deficient elements is by the

transfusion of normal blood. In acute purpura due to a thrombopenia, transfusion is usually necessary to tide the patient over the period while the platelets are low. While the tendency to bleed is permanent in true hemophilia, there are often exacerbations of the hemorrhagic tendency, so frequent small transfusions are often of the greatest help in the management of the abnormal bleeding. Hemorrhage of the newborn which probably is due to a deficiency in prothrombin should always be treated by transfusion. A deficiency in fibrinogen with resulting pathologic hemorrhage can be replaced only by new blood.

II. METHODS

Theoretically, the most desirable method of transfusion should be one whereby blood to which no foreign substance has been added is given with minimal manipulation and the least possible contact of the blood with the containing vessel or syringe. With a paraffined Kimpton tube, such requirements are met; however, an experienced transfusion team is required for the transfer of blood by this method. In a well-organized hospital such a procedure is possible, and this has been the method of choice by Dr. George Crile for many years and is used routinely on the surgical service in the Cleveland Clinic Hospital.

If the transfusion of blood were done only with a Kimpton tube, the usefulness of the procedure would be greatly decreased by reason of technical difficulties. Fortunately, citrated blood seems to be just as valuable as whole blood and transfusion of such blood can be performed with great ease without especial training or equipment. The citrate method of blood transfusion is by far the most widely used and fulfills all requirements, so it is usually the method of choice. Many citrate transfusions are poorly done in that little attention is given to minimal manipulation, to the gradual addition of the citrate as the blood is withdrawn from the donor, and to the prevention of any clotting whatsoever. Often the blood is allowed to flow from the donor into an open cylinder con-

taining the total amount of citrate needed for the total amount of blood to be withdrawn, stirred vigorously, allowed to cool and then run by gravity into the vein of the recipient. I have long used only a closed container with an attachment for supplying the citrate as the blood is withdrawn. Very little manipulation is required to mix the blood and citrate. Without transferring from the container, the blood is injected by pressure into the vein of the recipient. Many hundreds of transfusions by this method have convinced me that blood so given fulfills every requirement for the satisfactory transfer of blood in all clinical conditions requiring transfusion. The technic of the method mentioned above has been described in detail elsewhere.¹

If the blood volume is normal and the blood of the donor is normal, the hemoglobin of the recipient should be raised 10 per cent by the use of 500 cc. of blood and the red cell count elevated 500,000 per cubic millimeter. It is apparent that if the anemia is marked, several such transfusions are necessary, since it is seldom advisable to give more than 500 cc. at one time. If several transfusions are to be done, it is far better to give them in rapid succession. I prefer giving them at intervals of twenty-four or forty-eight hours. If the transfusion is given to combat toxemia, sepsis or shock, several are often needed and here also they should be given in rapid succession. In acute cases, it is often desirable to give even two a day employing 200 to 300 cc. of blood at each transfusion rather than 500 cc.

It is most important to type the blood of the donor and recipient most carefully. It is helpful to do this by mixing the cells of each with sera 2, 3, and 4 as well as the serum of each with cells 2, 3, and 4. Cross matching should always be done as an added precaution before the transfusion is carried out. It is usually best to have a donor of the same type as the recipient, but there is never any objection to using a group 4 (Moss) donor for any type. Except in a great emergency, a test for syphilis should always be done on the donor with one of the flocculation tests which are now so perfected.

No added time is required for this, as the test can be done while the typing and cross matching are being completed.

III. SUMMARY

This discussion emphasizes the wide range of usefulness of the transfusion of blood in medical treatment. In any clinical condition in which there is a lack of total circulating blood volume, a deficiency in any of the formed elements of the blood, an insufficient amount of substances dissolved in the substances of the blood, or less than the desired defense against infection, transfusion must be considered. Occasionally, the procedure is life-saving. Seldom, however, should transfusion be employed as a last resort; it should be used when the patient can still respond to the stimulating effect of the new blood. It is most important to give enough transfusions to secure the desired effect because one is often insufficient. If more than one is given, the interval between transfusions should usually be short. If the set-up is available for the transfer of whole blood, this is the method of choice. Citrated blood seems just as effective, however, and the transfusion of citrated blood is so simple it should be available at all times. In general practice, only by making the technic of blood transfusion simple can this most valuable therapeutic procedure have the wide usefulness it deserves.

CONSTITUTIONAL PSYCHOPATHIC PERSONALITIES THEIR RECOGNITION, DIAGNOSIS, AND MANAGE- MENT

LOUIS J. KARNOSH

POST-KRAEPELIN psychiatry has been able to draw out of the theological and metaphysical vagaries which obtained for many centuries certain scientifically delineated entities and to establish clear definitions thereof. Particularly has this been true of those disorders which concern the primary intellectual functions involving the phenomena of thinking, memory, association and orientation. Modern psychiatry has yet to deliver into a clear objective light those aberrations which deal with the life of feelings and impulse. Some of these latter disorders are actually in that unhappy position where they are neither accepted by the psychiatrist as true psychoses nor are they wholeheartedly regarded as problems belonging to the moralist and penologist.

Such is the miserable plight of those unfortunates who are commonly called constitutional psychopathic personalities, and whose condition has been aptly labeled "the stepchild of psychiatry." Because it lacks a respectable nosologic standing, it is misunderstood in the clinic, misinterpreted in the schoolroom and maltreated in the courts. Accepted by attorneys only when it offers a legal advantage and scorned by them when it does not, it is largely responsible for the notorious altercations in criminal procedures which at regular intervals give American medical jurisprudence a noisome reputation.

Some psychiatrists have offered the suggestion that the constitutional psychopath does not have a psychosis but possesses a "disease of personality." This appears to be a nice discrimination but is hardly tenable, for by the same token a patient with the "personality changes" of a frontal lobe tumor does not have a disease of the mind but merely harbors a "sick personality."

Such vague synecdoches as "personality" and "constitution" are frank admissions that an accurate concept of this entity is sadly wanting. And yet an entity it must be, for it is as frequently recognized by the practicing physician as it is by the psychiatrist—probably by intuition in both instances rather than by rational definition.

The confusion begins with the very first step necessary to establish an entity—namely its proper nosologic designation. A host of synonyms is employed to designate constitutional psychopathic personality, all of which are bitterly criticized, and no one term is universally accepted. Constitutional inferiority, pathological personality, moral imbecility, hypophrenia, discordant personality, defective delinquent, inadequate personality and a score of other terms contest with an equally large number of appellations which are dictated by the special behavior of the particular patient. In this group we have the recidivist, the pathological liar, the invert, the misanthrope, the pernicious braggart, the unstable, the impulsive, the vagrant type, etc.

When such disagreement exists as to terminology, to frame a satisfactory definition is an almost hopeless task. Stripped of theoretical and speculative elements, setting aside all fine-spun psychoanalytic considerations, and expressing the essential and specific criteria, the following definition is broad enough to include most of the fundamental features. Constitutional psychopathic personality is a condition either hereditary, congenital or acquired, affecting the emotional and volitional rather than the intellectual fields and manifested by certain anomalies of character which make satisfactory social adjustment impossible.¹

The constitutional psychopath is known better by his deeds than his true defects. A routine psychiatric examination, more often than not, reveals few objective data. Only a perusal of past performance, of a long succession of anti-social acts and society's repercussions to such acts reveals the typical career which brands the individual as belonging to this group.

While terminology is unsettled and definition is difficult,

the average psychiatrist has little difficulty in recognizing this human hybrid. Gathering the common denominators and excluding the rarer variations, a composite portrait of the constitutional psychopathic personality is readily obtained. He is a young individual, generally brought to the consulting room some time in his late teens, who shows little or no concern over his plight because he refuses to recognize he has any aberrations. Showing minimal intrapsychic tension, he appears sure of himself, has a defiant or sulky attitude, is distinctly egotistic and is ready to defend himself at all costs. The long recital by distracted parents of a record of selfishness, repeated petty misdemeanors, outbursts of rage, general instability and impulsive conduct, makes no impress upon his self-esteem, except to bring forth retaliations in the form of wilful lying, clever evasions, frank denial and shallow rationalization.

Training and discipline except for short sporadic periods does little good and the effect of punishment is nil. In addition to a career of instability, shiftlessness, coupled with lack of insight or ethical sense, the personality portrait is embellished with various distortions of the sexual life.

In the face of all this noxious behavior, the ordinary intellectual attainment may be normal or better than normal. Frequently this intellectual development may be spotted or scattered and quite often the superficial impression is gained that the patient is smart if not actually brilliant. A closer study reveals, however, the superficiality of mentation. A lack of inhibition of impulse, an emotional over-coloring of thought and action is sensed as well as an inability to express sound views, adequate summations and conclusions. There is a definite poverty of abstract induction. The constitutional psychopath shows what Kretschmer calls good "free-association thinking," *i. e.*, the ability to handle immediate concepts and percepts with vividness and dexterity, to give expression to thinking which is emotionally loaded. To stem such "short-circuited" mental activity, to draw on stored-up memories and complex association, to make critical and discriminative conclusions and derive broad concepts and thus to make his

behavior less primitive and naïve is beyond his powers. It is here that the constitutional psychopathic personality is defective. No meter stick, no quantitative quotient has yet been devised to measure this deficiency and give it an absolute value. Only by giving the patient free rein and by allowing him to face situations which call for calm deliberation, good judgment and careful analysis, is one able to gain a general knowledge of the fundamental weakness. Since no physical index or quantitative methodology is available to measure this, the temptation arises to call it a defect in the "total personality."

If the orthodox medical mind, which has been properly trained to think in terms of diagnosis, etiology and rational treatment, peruses the literature, the information is garnered that the disease—if it be a disease—is a biogenic one, a disturbance in the deeper structures of personality, a discordance in the impulse life, the temperament and the character elements of the individual. If the physician is venturesome, he can proceed into the elaborate classifications and subclassifications and into the exquisite psychological dissections of Schneider,² Kahn³ and others. Although these writers may claim otherwise, their excellent monographs can only be regarded as more detailed elaborations of symptomatology and serve only to furnish a clearer analysis of where in the psychological matrix the weakness exists, but this must not be mistaken for a true exposition of etiology. The welter of psychoanalytic enthusiasm has produced, as in other conditions, a fine-spun knowledge of how the psychopath performs but not why he so performs.

Boisen⁴ has set up a scheme wherein the inadequate personality behaves along certain patterns, these being impelled by a sense of failure as judged by personal standards. Among other things, the behavior is conditioned by the degree of awareness of the inadequacy. From this scheme, it is apparent that the constitutional psychopathic personality has little or no awareness of his defect and the end-results are obvious. Defending his ego to the last ditch, his means of solution are reduced to a few fairly fixed patterns. With an

attitude of flippancy and carelessness. he may find release of tension through clowning, making light of accepted standards and by associating with groups which live at a lower level of responsibility. Here is produced the rounder and the petty thief. He may maintain his self-esteem through constant depreciation of others and appear as the faultfinder and chronic misanthrope. Braggadocio is another method of bolstering self-respect, which sooner or later leads to pathological lying. wherein the delinquent portrays himself as a heroic, muchly abused or misunderstood person. A paranoidal misinterpretation of his troubles is another favorite response. Finally, when acutely assailed he may find temporary respite in self-pity, in claiming bodily ailments or by hysterical explosion. Here attempts at suicide—rarely genuine—amnesias and wandering spells are fugues which serve to help evade the critical situations.

All this is familiar ground to anyone who has dealt with more than two of these individuals. It only serves to make more poignant the problem and at best such exploration of the "depth" psychology offers only incidental and temporizing compromises in the direction of treatment.

Should psychiatry rest on the assumption that the psychopathic personality is an entity that belongs to the realm of depth psychology because of a paucity of physical signs? An expression on this had better be deferred for very good reasons. The rapidly unfolding data revealed by recent studies in cerebral physiology, the amazing growth of endocrinology and its invasions of pragmatic psychiatry, the profoundly significant revelations about human conduct and mental behavior in subjects who have survived removal of brain tissue for brain tumor extirpation and the improved technics of roentgenology, encephalography, and ventriculography are already revealing objective information which gives the problem another and more hopeful approach.

The so-called "personality changes" of fore-brain disease are rapidly becoming crystallized in diagnostic neurology so that they now exact almost the same respect as a positive

Babinski sign or a fixed pupil. The story of Phineas P. Gage is known to every neurologist and with certain reservations this worthy was in every respect a constitutional psychopathic personality for the twelve and a half years he survived his accident.

A number of brilliant resections of the frontal lobe by neurosurgeons have been reported in recent literature. Brickner's⁵ observations particularly emphasize that while ordinary intellectual functions are intact, there is a notable defect in the ability to make so-called "complex engrams," to synthesize a large group of ideas, to condense many minor experiences and to express broad judgments. In direct proportion, there is a tendency to more primitive mood swing and franker expression of emotionally colored ideas and impulse components in conduct.

These patients offer good examples of "control" cases in studying the phenomena of psychopathic personality. However, an outstanding difficulty in making fair comparisons is society's attitude. Any person who has miraculously survived an operation for bilateral frontal lobectomy is a very much sheltered and favored individual. He is not called upon to face crucial matters, not exposed to temptations nor asked to make grave decisions. Because the constitutional psychopath has an apparently intact body and a good intelligence he is expected to meet his problems adequately, is given freedom to display the entire catalogue of his deficiencies and when found wanting is punished forthwith.

If we are to give real meaning to the word "constitution," the growth factors involved in this deficiency must be sounded. The most malignant features of the constitutional psychopathic personality appear at the time when there are the greatest spurts in skeletal and visceral growth and when profound changes are taking place in the endocrine system. This suggests the possibility that the psychopath is a resultant of discordant development of all those elements which tend to harmonize the intellectual, emotional and instinctual integrations.

The brain attains its maximum size at the age of seven

years. However, from Flechsig's studies, complete myelinization of certain areas, notably the frontal lobes and parts of the temporal and parietal lobes, does not occur until the years of puberty. It can be inferred from this that the highest mental functions in the most complex association fields do not completely evolve until then. The question naturally arises: can injuries, inflammation or arrest of development occur in these zones and deficiency remain latent for many years before it is recognized or before it flowers into abnormal behavior? A fundamental error in our knowledge of this inadequacy may lie in the fact that cause and effect may be removed from each other by a wide space of time. An injury or inflammation may occur in infancy, leave no immediate after-effects and become relegated in the memory of parents as a matter of little consequence.

The following analysis of 63 cases presented as constitutional psychopathic personalities frankly emphasizes the organogenic approach to this problem.

Heredity.—Heredity cannot be ignored as an important contributing factor but because of our inadequate knowledge of human biogenics, no clarified statement can be made. Although in a large number of cases one parent or both were variously described as being irritable, erratic, or unstable, just as often both father and mother were balanced, industrious, socially well-acclaimed individuals. Several were described as being subject to sharp cycling of mood and a fair number were said to have been high-strung, over-refined and specially gifted in certain intellectual fields. Psychopathic personality in other siblings was found in only 2 cases.

Birth Injuries.—Intracranial birth injuries are probably more frequent than is ordinarily suspected. Lumbar punctures in newborn infants have disclosed bloody spinal fluid in as many as 40 per cent. Obviously, the vast majority of these injuries are trivial and leave no residue. Injuries over "silent areas" may be extensive and may not manifest themselves until such zones are expected to mature. Even such refined technic as encephalography will not reveal the locus

or the extent of such injury early enough to anticipate abnormal development. Only 1 case of the 63 studied was definitely regarded as a true birth palsy and the encephalogram revealed a porencephalic defect in the left frontal lobe.

Home Factors.—Unlike other functional nervous disorders of youth, the psychopathic personality is not essentially a product of the broken or disordered home. Only 5 of the 63 patients could point to gross incompatibility of the parents as a source of irritation, and in only one was this an immediate cause of misbehavior. Jealousy of other siblings is a more outstanding psychogenic component, being noted in over 40 per cent of the cases. Obviously, this must be recognized as more of a symptom of the basic deficiency rather than a true causative factor, for the psychopath is compelled to take advantage of every rationalizing device to maintain his self-esteem. Four of the patients were foster children and here the hereditary component must be given equal consideration with the many psychogenic factors which are bound to emerge with such a social status.

Childhood Diseases.—These were found to be no more frequently encountered than in the normal population statistics. However, in more than half of the cases a particular febrile illness was described as being very severe, prolonged and followed by a protracted convalescence. Measles, whooping cough and scarlet fever in the order given were found to be the worst offenders as shown by the following:

Severe Illness:

Measles	16
Whooping cough	15
Scarlet fever	10
Empyema and pneumonia	2

Minor Illness:

Acute rheumatic fever	2
Chorea	4
Malnutrition	4
	—

Total	54
-------	----

No History of Childhood Disease	10
---------------------------------	----

If anything, infectious diseases are outstanding, not particularly because of their specific nature but because of severity. Measles and whooping cough are not infrequently associated with cerebral complications and a mild encephalitis may be a residue in such infections. Whether or not this occurred in this group cannot be proved but should be regarded as a probability, for the sequelae were found to be not unlike the milder cases of juvenile (lethargic) encephalitis.

Trauma.—Injury to the head in early life is a very common incident in the lives of normal children. Trauma to the head occurred in about 12 per cent of the patients in this series but in only 4 can it be said that it was serious. In a fifth the injury consisted of severe burns about the mouth and throat from lye after which the behavior disorders appeared. Injuries to parts other than the head were not included.

Bodily and Endocrine Developments.—Some writers have found as many as 40 per cent of these disturbances were associated with endocrine imbalances. In this group 24 were notably dysplastic. Because biogenic assays of endocrine status are as yet difficult and expensive, complete knowledge of this feature of the psychopath is a matter for further investigation. Of the 12 who were more carefully scrutinized in this respect, 10 males were consistently eunuchoid in constitution, and bone growth was ahead of sexual development. All 10 showed a bone age three or four years above chronological age. In contrast, the beard and genitalia were immature. In 6 of these, the male sex hormone assays were low; in 9 the metabolic rate was lower than normal. In all but 1 of the 10 the hypometabolism was regarded as an expression of hypogonadism. Only one had a potential diabetes with a disturbed sugar tolerance.

Twelve psychopathic girls were definitely suffering with hypo-ovarianism and 2 on the other hand were sexually overdeveloped and sexually delinquent. Stealing and lying was the common misbehavior of those with deficient ovarian functions.

This smattering of endocrine study in psychopathic constitution revealed endocrine imbalance in over 38 per cent of the subjects. Partridge,⁶ who emphasized this feature, found 26 per cent were so afflicted, while McCartney,⁷ who was more impressed by the anomalies of character, believed that only 3 per cent were in this dysplastic group. The theory that in many cases psychopathic personality is an expression of uneven growth seems to have good support and may explain why not a few young psychopaths tend to improve as they grow older because development evens out or compensatory over-function occurs in other endocrine structures.

Intracranial Disease.—If all 63 cases had been studied by such methods as encephalography, ventriculography and intracranial surgical exploration, it is possible that some type of encephalopathy would be discovered in a larger number. For various reasons, 22 of the 63 cases were subjected to the above measures, largely because there were neurologic findings justifying such diagnostic technics. Fourteen of these were found to have had positive findings. These were merely gross lesions and no method other than actual brain biopsy can be utilized to discover microscopic changes. Hence, it is impossible to determine how many individuals showing psychopathic constitution actually have true encephalopathy. The findings which are recorded in the table below are striking, not only because of the diversity of the lesions, but also because there is a preponderance of these lesions in the frontal regions and about the neuropituitary portions of the brain stem.

TABLE OF ENCEPHALOPATHIES FOUND IN 22 CASES REGARDED AS CONSTITUTIONAL
PSYCHOPATHIC PERSONALITIES

Internal hydrocephalus	6
Distention of third ventricle	1
Tumors of frontal lobe	2
Cyst of frontal lobe	1
Atrophy of frontal lobes	3
Chiasmal arachnoiditis	1
Porencephaly in the frontal lobes (birth palsy)	1
Negative findings	7
	<hr/> 22

Naturally when a specific brain disease is established, the diagnosis is changed from that of psychopathic constitution to one of true encephalopathy. In this irregular perusal of 63 cases, 22 per cent were found to have an organic basis in the central nervous system for their unnatural behavior (Fig. 190). If we accept the postulates laid down in reference to

Fig. 190.—General loci of lesions found in 15 cases clinically presented as constitutional psychopathic personalities.

frontal-lobe function it can be said that at least some of the symptoms manifested by these patients are evidences of frontal lobe deficiency.

TREATMENT

That organic factors are present in psychopathic personalities is generally conceded. Whether or not these are primary causes or merely contributory elements is not clearly shown. However, these objective findings suggest that treatment should be more than perfunctory and that all psychopathic personalities should not be consigned at once to the custodial scrap heap. As mentioned before, an unknown per-

centage gradually improves spontaneously after growth distortions have disappeared. If there is a history of severe infantile febrile disease, one should try fever treatment with typhoid or other foreign protein. Two patients showed marked improvement after such treatment. Schneider² and others have been impressed by the cyclic or periodic activity of the psychopath, and frequently relatives are well aware of the prodromal signs of such cycles. In such cases, the use of bromides and other sedatives may stem a burst of abnormal and impulsive activity. Glandular treatment, when indicated, is to be recommended, but the exquisite diagnosis and therapeutic management of such features had better be turned over to an expert endocrinologist. x-Ray examination of the skull and encephalography, when convenient, should be resorted to, if the faintest suspicion of intracranial pathology exists.

Nobody will deny that the psychopathic personality requires even closer supervision than a psychotic patient. Adjustment to a simple, monotonous routine is impossible because by virtue of his vivid emotionality the psychopath abhors such an existence. Yet under a rigid discipline in an institution this patient is generally normal in behavior.

In most states there is no accepted legal definition of psychopathic personality. This state of affairs does not allow indefinite incarceration of such patients and the vast majority are allowed to run the gamut of reform schools, detention hospitals, prisons and work farms. Until special public institutions for the psychopathic individual are provided, the institutional care of the psychopath shall remain at best a sketchy matter.

THE DIAGNOSIS AND NEWER TREATMENT OF GONORRHEAL VULVOVAGINITIS IN CHILDREN

WILLIAM J. ENGEL

IN handling any case of vaginitis in young girls, it is obviously first necessary to establish a diagnosis, and in so doing, to remember that not all cases of vaginitis in children are due to the gonococcus. All cases may be classified as acute or chronic and further subdivided etiologically into the gonorrheal and nongonorrheal forms.

The symptoms in any case of vaginitis may be much the same, consisting of burning or itching and irritation about the vulva and examination reveals a reddened vaginal orifice from which comes a purulent or seropurulent discharge. Not infrequently a urethritis and cystitis may give rise to burning and frequency of urination.

The diagnosis is finally established by careful examination of a smear of the discharge to which a Gram stain is applied. The finding of typical gram-negative intracellular diplococci morphologically identical with the gonococcus is sufficient to establish the diagnosis of gonorrheal vaginitis. Confirmatory evidence may be had by obtaining a culture of the organism, but this is rather difficult to accomplish on ordinary culture media and hardly necessary in most cases.

Acute nongonorrheal vaginitis is occasionally encountered during the course of an acute infectious disease, particularly scarlet fever, influenza and occasionally diphtheria. The latter is characterized by the presence of a membrane while in the others of this type the discharge is very thin and watery and tends to subside spontaneously in a few days.

Chronic nongonorrheal vaginitis may be due to a constitutional disease associated with malnutrition and uncleanness. Also in any chronic vaginitis, it is important to rule out the presence of foreign bodies and to look for parasites in the vaginal canal.

Gonorrheal vaginitis begins as an acute inflammation from which it progresses to a chronic state in the majority of cases. It is usually contracted innocently from infected linens or toilet seats and may be carried directly from an infected parent or nursemaid. Once introduced, the gonococci flourish on the thin delicate mucous membrane of the immature vaginal canal and eventually penetrate deep between the interstices of the epithelial cells into the submucosa, and the inflammation frequently penetrates even to the muscular layer. Fortunately, at the younger ages, Skene's glands, Bartholin's gland and the endocervical glands are not developed, so they cannot harbor the infection. Rarely if ever does the infection travel up to the tubes, but not infrequently there may be an associated gonorrheal proctitis which must be recognized and treated if a cure is to be obtained.

This disease is highly contagious and an outbreak in a children's ward of a hospital or in a school may spread rapidly to epidemic proportions. It is highly important, therefore, to exercise rigid precautions when a case is discovered. These include complete isolation and careful sterilization of diapers, linens and toilet articles. If a case develops in a children's ward of a hospital, the entire ward should be isolated and all the other children carefully examined at frequent intervals. In short, one cannot be too careful in the management of these cases to prevent the spread of this distressing infection.

Until 1933, when Lewis¹ suggested the use of theelin, the treatment of this disease had been notoriously unsatisfactory. Practically all the known germicides and antiseptics had been tried and recommended but the multitude of methods suggested was in itself evidence of the inefficacy of any one. One needs only to recall the depth to which this infection travels to understand the futility of attempting to destroy the organ-

isms by applying germicides to the vaginal mucous membrane. For the purpose of cleanliness, irrigations with antiseptic solutions are useful and should be employed as will be described, but we should not lead ourselves to believe that we are destroying the gonococci in this manner.

The background of the use of ovarian hormone in the treatment of this disease is of interest. In 1928 Edgar Allen² had shown that injections of ovarian hormone for twenty-one days into the immature female monkey caused the vaginal epithelium to increase in thickness from 4 to 8 layers in the controls, to 30 or more layers in the treated animals, and furthermore this was associated with the development of a cornified layer and the appearance of many desquamated epithelial cells in the vaginal smears. There was an associated development of the cervical glands which were invaded by leukocytes, and the endometrium was built up at most to a midinterval phase.

It is known that gonorrheal vaginitis in children tends to subside spontaneously at or before puberty, when the vaginal mucous membranes become adult in type and furthermore, that the gonococcus does not invade the adult vaginal mucosa. Reasoning from these facts, Lewis¹ conceived the idea of artificially changing the vaginal mucosa of the child by the use of theelin, thereby rendering it unfavorable to invasion by the gonococcus. Its use appeared to be harmless, since Hartman³ had shown that a dose sufficient to produce changes in the vaginal epithelium was much below that which might lead to injurious changes and uterine bleeding, and furthermore, Allen² had shown that all changes returned to normal in four to six weeks after treatment with ovarian hormone was discontinued. From the present available clinical reports, it would appear that the administration of this hormone to children is without deleterious effects, although it should be used with caution and all possible secondary effects carefully noted.

Lewis reported good results in the treatment of 4 cases of chronic and 4 of acute gonorrheal vaginitis. Seven patients

were apparently cured and free from recurrence while recurrence was noted in only one. Huberman and Israeloff⁴ later reported good results in 6 patients following the use of amniotin. In one of their cases the amniotin was administered by mouth and the patient was clinically cured within eight weeks and this was followed by no recurrence. This latter is of particular importance because of the obvious advantage of oral administration in children. Other reports by Nabarro and Signy,⁵ Reading,⁶ and Brown⁷ attest to the efficacy of estrogenic hormone in the treatment of this disease. In all cases, the disease appears to have been cured in a shorter period of time and with lasting results. The appearance of desquamated epithelial cells in the vaginal smear is taken to be the criteria of adequate treatment and associated with this the purulent discharge changes to a thick, dry adult type of leukorrhea. Following cessation of treatment, there is an involution of the vaginal structures.

Let us then outline a satisfactory treatment for the child with gonorrheal vulvovaginitis. The treatment is the same whether it be an acute or a chronic infection, although it has been noted that the chronic case usually clears up more rapidly following treatment with estrogenic hormone.

The patient should be started immediately on estrogenic hormone (such as theelin, amniotin, progynon or menformon) and this should be given daily until negative vaginal smears are obtained. This hormone may be given hypodermically or by mouth. One hundred rat units daily is usually adequate if hypodermic injection is used, while about five times this dose should be used in case of oral administration. From all clinical and experimental observations, it appears that oral administration is entirely effective, and its obvious advantage in children should make it the method of choice. Vaginal smears should be made at frequent intervals, and the effectiveness of the treatment is judged by the appearance of numerous desquamated epithelial cells in the smear.

In addition to this, the vaginal canal should be irrigated carefully each day and for this purpose, one may select from

a number of solutions, although we have found a 1:5000 solution of potassium permanganate quite suitable. A soft rubber catheter introduced into the vagina serves admirably as an instrument for this purpose and usually is less objectionable to the child than a rigid instrument. The solution should be comfortably hot and at least a quart used at each irrigation.

Other measures are seldom necessary in the average case. Should an infection prove unusually obstinate, however, the cause may be a resistant cervicitis which should be treated by cauterization of the cervix with 20 per cent silver nitrate solution or linear cauterization as suggested by Titus and Notes.⁸ Another cause may be a proctitis which should be treated by low rectal irrigations followed by the instillation into the rectum of a 4 per cent solution of argyrol or $\frac{1}{2}$ per cent protargol.

Crossen⁹ has reported good results by the use of diathermy which may be employed to good advantage, especially if there is any evidence of pelvic inflammation.

With any form of treatment, however, the possibility of recurrence is to be borne in mind, and all patients should be followed carefully to assure a lasting cure. Reinfection may also occur, so that all possible sources of infection in the child's environment (parents, nursemaids, etc.) must be carefully controlled.

Fortunately, it is rare for any effects of a vulvovaginitis to persist into adult life; therefore, one can give a good prognosis once a cure has been established.

TREATMENT OF CHRONIC HYPOGLYCEMIA

E. PERRY McCULLAGH

It is the custom at present to consider cases of chronic hypoglycemia without obvious cause to be instances of hyperinsulinism. This may or may not be warranted, since our present methods do not make it possible to measure with accuracy such factors as the function of the liver, the pituitary or adrenals in this respect.

Some of the common causes of hypoglycemia which must be considered are:

1. **Excess of Insulin.**—This may follow injections of insulin in diabetics or it may be associated with hyperactivity of the insulogenic function and in some cases has been associated with hypertrophy of the islands of Langerhans or with benign or malignant tumors. Hypoglycemia occurs very frequently four or five hours after a large amount of glucose has been taken such as in a glucose tolerance test. In the majority of instances, this is not associated with symptoms and it presumably is the result of stimulation of insulin production. Hypoglycemic reactions occur in some diabetics apart from insulin medication.

2. **Deficient Glycogenesis.**—This may be present following destruction of the liver by poisons, acute yellow atrophy, and extensive destruction by tumors. Probably cirrhosis is a factor in some cases. Hypoglycemia has been shown to be associated with extensive fatty metamorphosis of the liver in late diabetes.¹ It seems probable that functional liver disease may produce the same effect. Muscle wasting may produce hypoglycemia and the mechanism in some instances appears to be on the basis of glycogen deficiency. Starvation, excessive exercise, and occasionally loss of sugar by lactation or in renal glycosuria may be factors.

3. **Endocrine Disorders Affecting Other Glands.**—The influence of the pituitary gland on sugar metabolism is obvious in cases of pituitary tumors and in cases of extensive pituitary damage such as in Simmond's disease. Hypothyroidism is frequently associated with hypoglycemia but in both the above instances the hypoglycemia may be asymptomatic. Disease of the suprarenal glands may produce a similar result and hypoglycemia is an almost constant finding in Addison's disease and has been reported in the presence of adrenal tumor.²

4. **Organic Nervous Disease.**—The presence of organic nervous disease must be ruled out. We have seen abnormally low glucose tolerance curves in cases of brain tumor.

No discussion will be made here of the diagnosis of hyperinsulinism and the above groups are cited simply to emphasize the fact that the causes of hypoglycemia are multiple, and that the condition does not always produce symptoms.

The symptoms of the condition are extremely variable. In mild cases the common symptoms are excessive hunger, weakness, tremor, excessive sweating, anxiety and inability to concentrate the thoughts. In more severe cases, mental lapses, grand mal, violent delirium and death have been described.

When the condition is suspected, the chief points in diagnosis are that the symptoms are relieved by food or glucose and can be shown to be associated with blood sugar levels which usually are definitely below 70 mg. per 100 cc.

Many conditions such as psychoneuroses, psychoses, encephalitis, intracranial neoplasm, epilepsy, alcoholic intoxication and coma from various causes must be borne in mind as sources of similar symptoms.

When all these factors are considered, it is obvious that no standard treatment can be applied in all cases, but must be varied in accordance with the cause of the condition. The most satisfactory treatment in most instances is by dietary measures, which may be supplemented in some cases with endocrine therapy or drug therapy and in the more severe instances surgery must be considered.

The dietary principles which we have found most effec-

tive are (1) frequent feedings and (2) the use of high fat, low carbohydrate diets.

It is generally conceded that a high intake of carbohydrate may increase the tolerance to carbohydrate and tend to lower the blood sugar. This is true not only in nondiabetics but in many diabetics as well, and has led to the general use of much higher intake of carbohydrate in diabetics than was formerly used.

Fig. 191.

The accompanying graphs (Figs. 191–198) show the rather marked effect that may be observed in suitable cases.

The patient was a middle-aged woman who entered the hospital with a history of rather marked alcoholism and numbness and pain in the extremities which was thought to be due to vitamin deficiency, since her food intake had been very low for several weeks.

Figure 191 shows the glucose curve after 100 Gm. of glucose had been taken by mouth.

A tentative diagnosis of diabetes mellitus was made and the patient was placed on a high carbohydrate diet, quickly increasing the intake to 280 Gm. per day. At this time the protein intake was 86 Gm. and the fat intake was 60 Gm.

Twenty days later the glucose tolerance was repeated and the curve is shown in Fig. 192.

It has been recognized for a long time that low carbohydrate, high fat diets may lead to elevation of blood sugar levels. In 1923 the effects of diets in the treatment of epilepsy were reported by Weeks, Renner, Allen and Wishart.³ These in-

Fig. 192.

investigators placed 6 patients on very high fat, extremely low carbohydrate diets for forty-eight days. In every patient hyperglycemia gradually developed. The highest figure reached was 357 mg. per 100 cc.

The usual explanation of the mechanism is that since the blood sugar rises but little, insulin production is not stimulated. In consequence, the fall in blood sugar levels which would ordinarily take place does not occur. On this basis, Harris⁴ suggests the use of daily diets of 90 Gm. carbohydrate, 60 Gm. protein and 180 Gm. of fat in the treatment of hyperinsulinism. This he divides into 7 feedings per day. For

obese patients he suggests the use of a diet containing 90 Gm. carbohydrate, 60 Gm. protein and 60 Gm. of fat, making a total caloric intake of 1140, while in underweight individuals, 90 Gm. carbohydrate, 60 to 75 Gm. protein and 200 to 300 Gm. of fat are used.

Such cases as those reported by Shepardson⁵ illustrate the value of this treatment. In one case of hypoglycemia treated with a high fat diet ranging from 100 Gm. carbohydrate, 80 to 90 Gm. protein and 200 to 280 Gm. fat, the blood sugar levels four and one-half and five hours after meals rose from 66 and 60 mg. per 100 cc. preceding treatment to 98 mg. per 100 cc. five and one-half hours P. c. one week later, and more than three weeks after treatment was begun, levels rang-

Fig. 193.

ing from 97 to 117 mg. per 100 cc. five hours P. c. were found. These changes were associated with marked clinical benefit. In another case, the blood sugars rose on a high fat diet from 58 mg. per 100 cc. before treatment to 81 mg. per 100 cc. one month after treatment was instituted.

The type of result which may be observed is illustrated by the following case: a white man, twenty-nine years of age, in 1932 complained that for nine years he had had frequent spells of weakness, nervousness and perspiring of the entire body. At times this was accompanied by a tendency to stutter and to be confused mentally. He had not associated his symptoms with meals, as he felt very fatigued most of the time. He had been forced to stop work for several months

because of poor endurance, severe headaches and marked insomnia. On June 2, 1932, his glucose tolerance was measured using 100 Gm. of glucose orally. The results are shown in Fig. 193.

A diagnosis of chronic hypoglycemia was made and a diet was prescribed which contained approximately 105 Gm. of carbohydrate, 75 Gm. of protein and 250 Gm. of fat with food between meals and at bedtime. Within two weeks the symptoms had disappeared entirely. Headaches which were previously frequent, severe and sustained for many days at a time have not occurred more than about once a year since treatment. A severe headache was precipitated by a glucose tolerance test which was done January 8, 1935 (Fig. 194).

Fig. 194.

While the fasting blood glucose level is not altered, there is a distinct change in the tolerance.

A second case illustrating this point may be cited. A white woman, forty-one years of age, was referred to Dr. George Crile by Dr. W. E. Blanchard with a diagnosis of chronic cholecystitis and hyperinsulinism with possible pancreatic tumor. It required a very careful history to elicit the fact that the chronic fatigue was aggravated by spells of weakness and sweating. Neither were the attacks always relieved by eating. Cholecystogram revealed a nonfunctioning gallbladder with stones. On August 7, 1935, glucose tolerance test was given, using 100 Gm. of glucose orally. The blood sugar levels are shown in Fig. 195.

A diet was instituted which contained 100 Gm. carbohydrate, 70 Gm. protein, and 150 Gm. of fat, with feedings between meals and at bedtime. One month following our first

Fig. 195.

Fig. 196.

examination, the glucose tolerance test was repeated and the results are shown in Fig. 196. At about the fourth hour the patient had an attack of marked weakness, trembling and

sweating which coincided exactly in her mind with her previous attacks.

Cholecystectomy was performed on September 9, 1935, and an uneventful convalescence followed. The diet was continued. No hypoglycemic reactions occurred and general strength has continued to increase.

A glucose tolerance test on November 8, 1935, showed the results seen in Fig. 197. During this test 0.63 Gm. of sugar appeared in the urine. Because of the very marked effect on carbohydrate tolerance and because of the tendency to glyco-

Fig. 197.

suria, the question was raised as to whether or not such a response was due entirely to the effect of the diet or whether, as in some cases, other factors were at work which were carrying this patient toward diabetes.

The problem was explained to the patient and again her cooperation was solicited. On January 4, 1936, a high carbohydrate diet was instituted which contained 275 Gm. carbohydrate, 85 Gm. protein and 70 Gm. fat per day with nourishment between meals and at bedtime. On January 29, 1936, the glucose tolerance was again performed with the result shown in Fig. 198.

It seems to have been thoroughly established in this case that the type of low carbohydrate, high fat diet used allowed the tolerance for glucose to decrease and blood sugar levels to rise, even to diabetic levels. The high carbohydrate diet, on the other hand, was capable of forcing the blood sugar levels downward and increasing glucose tolerance markedly.

It might be added that the diet in this case is accurately weighed under the direct supervision of a skilled dietitian.

If diets in such cases are to be efficient, they must be taught as accurately as diets are taught to a diabetic or they will lose

Fig. 198.

their value. Samples of high fat diets, of various caloric value which may be used in the treatment of hypoglycemia, are appended.

For the treatment of an acute attack of hypoglycemia, nothing is as effective as intravenous glucose which may be given in a 25 or 50 per cent solution. This is especially valuable in the case of an unconscious patient. Even in unconsciousness, dry sugar placed in the mouth may be sufficient. The rectal administration of glucose is of little value. If the patient is conscious, orange juice alone or with from 10 to

30 Gm. of glucose or cane sugar is almost always promptly effective. One-half to 1 cc. of 1:1000 solution of epinephrine may be of help. Ephedrine and caffeine are of less value.

Various endocrine products have been suggested for the treatment of hypoglycemia. John⁶ describes a method of treatment in which insulin is used to prevent the rise of blood sugar in an attempt to offset in turn the stimulation of the pancreas and the production of excessive amounts of insulin. Although the patients may be relieved by such measures, it has not been shown that there is the marked change in tolerance which may follow the use of high fat, low carbohydrate diets. The value of the method has not as yet been confirmed adequately.

The use of thyroid medication is indicated if the metabolism is low but little effect can be expected from it unless sufficient amounts are given to raise the metabolic rate to heights which are undesirable. Ziskind,⁷ for instance, reports no increase in blood sugar levels after giving a patient 34 grains of thyroid per day which was sufficient to raise his basal metabolic rate to +52 per cent.

Very little benefit is obtained from the use of pituitary extracts such as are now available in forms to be given either by mouth or hypodermically, and little or nothing is to be gained by giving adrenal substance orally. x-Ray radiation of the pancreas has apparently not been given sufficient trial to warrant any comments regarding its value. The diabotogenic hormone of the pituitary gland promises to be of value when it becomes available.

When frequent feedings, diets, and other measures fail to control the symptoms, severe functional hyperinsulinism is to be considered, tumor of the pancreas may be present and surgery is indicated. On the whole, however, operative results have been poor except in those instances where a pancreatic tumor has been removed. It is to be hoped that improvement in surgical technic and removal of larger proportions of the pancreas than has been practiced in the past, will give more complete and consistent relief in severe cases in the future.

I. LOW CALORIE DIET

Carbohydrate, 60 Gm.; protein, 60 Gm.; fat, 80 Gm. Total calories, 1200.

	Grams.	Household measure.
<i>Breakfast:</i>		
Fruit, 10 per cent.	50	$\frac{1}{2}$ serving (see list)
or Tomato juice, 5 per cent.	100	
Egg		1
Butter.	5	$\frac{1}{2}$ square
Whole milk.	100	$\frac{1}{2}$ glass
10.00 A. M.:		
Whole milk.	100	$\frac{1}{2}$ glass
<i>Luncheon:</i>		
Clear broth.		as desired
Meat.	60	2 ounces
Cooked vegetable, 5 per cent.	100	$\frac{1}{2}$ cup
Butter.	10	1 square
Fruit, 10 per cent.	50	$\frac{1}{2}$ serving (see list)
3.00 P. M.:		
Whole milk.	100	$\frac{1}{2}$ glass
<i>Dinner:</i>		
Meat.	90	3 ounces
Cooked vegetable, 5 per cent.	100	$\frac{1}{2}$ cup
Raw vegetable, 5 per cent.	100	1 cup
Butter.	10	1 square
Whole milk.	100	$\frac{1}{2}$ glass
Fruit, 10 per cent.	50	$\frac{1}{2}$ serving (see list)
9.00 P. M.:		
Whole milk.	100	$\frac{1}{2}$ glass
Cream, 20 per cent fat.	100	$\frac{1}{2}$ glass

*Sample Menu**Breakfast:*

$\frac{1}{2}$ glass tomato juice
 1 coddled egg
 $\frac{1}{2}$ square of butter
 $\frac{1}{2}$ glass whole milk
 10.00 A. M.:
 $\frac{1}{2}$ glass whole milk

Luncheon:

Beef broth, 1 cup
 2 ounces assorted cold cuts

$\frac{1}{2}$ cup sliced tomatoes
 $\frac{1}{2}$ cup cold asparagus
 1 teaspoonful mayonnaise
 $\frac{1}{2}$ cup cantaloupe

3.00 P. M.

$\frac{1}{2}$ glass whole milk

Dinner:

Consomme
 3 ounces steak
 $\frac{1}{2}$ cup brussels sprouts
 1 cup celery tips
 1 square butter
 $\frac{1}{2}$ glass whole milk
 1 slice pineapple

9.00 P. M.

$\frac{1}{2}$ glass milk
 $\frac{1}{2}$ glass 20 per cent cream

II. MEDIUM CALORIC VALUE

Carbohydrate, 90 Gm.; protein, 75 Gm.; fat, 160 Gm. Total calories, 2100.

	Grams.	Household measure.
<i>Breakfast:</i>		
Fruit, 10 per cent.	100	1 serving (see list)
Egg		1
Butter	10	1 square
Whole milk	100	$\frac{1}{2}$ glass
Cream, 20 per cent.	100	$\frac{1}{2}$ glass
10.00 A. M.		
Whole milk	100	$\frac{1}{2}$ glass
Cream, 20 per cent.	100	$\frac{1}{2}$ glass
<i>Luncheon:</i>		
Broth		as desired
Meat	90	3 ounces
Cooked vegetables, 5 per cent.	100	$\frac{1}{2}$ cup
Butter	20	2 squares
Fruit, 10 per cent.	100	1 serving (see list)
3.00 P. M.		
Whole milk	100	$\frac{1}{2}$ glass
Cream, 20 per cent.	100	$\frac{1}{2}$ glass

Dinner:

Broth.....		as desired
Meat.....	90	3 ounces
Cooked vegetable, 5 per cent	100	$\frac{1}{2}$ cup
Raw vegetable, 5 per cent	100	1 cup
Butter.....	15	1 $\frac{1}{2}$ squares
Whole milk.....	100	$\frac{1}{2}$ glass
Fruit.....	100	1 serving (see list)

9.00 P. M.

Whole milk ..	100	$\frac{1}{2}$ glass
Cream, 20 per cent	100	$\frac{1}{2}$ glass

*Sample Menu**Breakfast:*

- $\frac{1}{2}$ glass orange juice
- 1 egg—soft-boiled
- 1 square butter
- $\frac{1}{2}$ glass milk
- $\frac{1}{2}$ glass, 20 per cent cream

10.00 A. M.

- $\frac{1}{2}$ glass milk
- $\frac{1}{2}$ glass, 20 per cent cream

Luncheon:

- Broiled liver, 3 ounces
- $\frac{1}{2}$ cup cooked broccoli
- 2 squares butter
- 1 small baked apple

3.00 P. M.

- $\frac{1}{2}$ glass milk
- $\frac{1}{2}$ glass, 20 per cent cream

Dinner:

- Broth, 1 cup
- 3 ounces roast lamb
- $\frac{1}{2}$ cup string beans
- 1 cup mixed vegetable salad
- 1 $\frac{1}{2}$ squares butter
- $\frac{1}{2}$ glass milk
- $\frac{1}{2}$ cup unsweetened canned cherries

9.00 P. M.

- $\frac{1}{2}$ glass milk
- $\frac{1}{2}$ glass 20 per cent cream

III. HIGH CALORIE DIET

Carbohydrate, 100 Gm.; protein, 75 Gm.; fat, 250 Gm. Total calories, 3000.

	Grams.	Household measure.
<i>Breakfast:</i>		
Fruit, 10 per cent.	100	1 serving (see list)
Egg		1
Toast,	15	1 thin slice
Butter,	30	3 squares
Cream, 20 per cent.	100	$\frac{1}{2}$ glass
Whole milk,	100	$\frac{1}{2}$ glass
10.00 A. M.		
Cream, 20 per cent.	200	1 glass
<i>Luncheon:</i>		
Meat,	90	3 ounces
Cooked vegetable, 5 per cent.	100	$\frac{1}{2}$ cup
Butter,	25	2 $\frac{1}{2}$ squares
Fruit, 10 per cent.	100	1 serving (see list)
3.00 P. M.		
Cream, 20 per cent.	200	1 glass
<i>Dinner:</i>		
Broth,		as desired
Meat,	120	4 ounces
Cooked vegetable, 5 per cent.	100	$\frac{1}{2}$ cup
Raw vegetable, 5 per cent.	100	$\frac{1}{2}$ cup
Butter,	40	4 squares
Bread,	15	1 thin slice
Fruit, 10 per cent.	100	1 serving (see list)
9.00 P. M.		
Cream, 20 per cent.	200	1 glass

*Sample Menu**Breakfast:*

- $\frac{1}{2}$ glass orange juice
- 1 poached egg
- 1 thin slice toast
- 3 squares butter
- $\frac{1}{2}$ glass whole milk
- $\frac{1}{2}$ glass 20 per cent cream

10.00 A. M.

- 1 glass 20 per cent cream

Luncheon:

- 3 ounces meat balls
- $\frac{1}{2}$ cup cooked tomatoes
- $2\frac{1}{2}$ squares butter
- 1 medium sized peach

3.00 P. M.

- 1 glass 20 per cent cream

Dinner:

- Broth, 1 cup
- 4 ounces roast chicken
- $\frac{1}{2}$ cup spinach
- 1 cup lettuce hearts
- 3 teaspoonfuls mayonnaise
- $2\frac{1}{2}$ squares butter
- 1 thin slice of bread
- $1\frac{1}{2}$ cup strawberries

9.00 P. M.

- 1 glass 20 per cent cream

The 3000 calorie diet above has sufficient fat content as compared to carbohydrates to produce ketosis in some individuals, so that it is advisable to raise the fat content to this level gradually.

Since only 5 per cent vegetables are used, little error will arise from using a standard 8 ounce measuring cup to measure these. The glasses referred to are 6 ounce drinking glasses.

One square of butter is a slice from a quarter pound and will measure approximately $1\frac{1}{4} \times 1\frac{1}{4} \times \frac{3}{8}$ inches. A thin slice of bread is a piece cut from a standard square loaf and is $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{1}{4}$ inches.

One serving of fruit selected from any of the following may be substituted for fruit anywhere in the lists given. Unsweetened cooked fruit may be measured the same as uncooked fruit.

A list of 5 per cent vegetables is also appended.

Each of the following contains 10 grams of carbohydrate and is one serving:

Apple (raw)	$\frac{1}{2}$ apple, 3 inches in diameter
Applesauce	6 tablespoonfuls
Apricots	2 apricots, $1\frac{1}{2}$ inches in diameter
Cantaloupe	1 cup or $\frac{2}{3}$ of a melon, $4\frac{1}{4}$ inches in diameter
Cherries (sour)	$\frac{1}{2}$ cup
Cherries (sweet)	$\frac{1}{2}$ cup
Cranberries	1 cup
Grapefruit	$\frac{1}{2}$ grapefruit, 4 inches in diameter
Grapefruit juice	$\frac{1}{2}$ glass
Grapes	1 small bunch or 18 grapes
Honeydew melon	$\frac{1}{2}$ cup, cubed

Orange	1 orange (California 150's—Diam. 3") (Florida 176's—Diam. 2½")
Orange juice	½ glass
Peach	1 medium sized
Pear	½ large sized
Pineapple	½ cup diced or 2 slices
Plums	2—1½ inches in diameter
Raspberries	¾ cup
Rhubarb (cooked)	1½ cups
Tangerines	1—3 inches in diameter
Tomato juice	1 glass
Strawberries	1½ cups

Vegetables, 5 per cent:

Asparagus	Eggplant	Romaine
Beet greens	Green pepper	Sauerkraut
Broccoli	Kale	Spinach
Brussels sprouts	Kohlrabi	String beans
Cabbage	Leeks	Swiss chard
Cauliflower	Lettuce	Tomatoes
Celery	Mushrooms	Turnip tops
Celery cabbage	Okra	Wax beans
Cucumbers	Parsley	Summer squash
Endive	Radishes	Watercress

Lambia intestinalis in bile, *Nov.*, 680
 Laryngeal neuralgia, superior, relief of, *Jan.*, 1029
 Laryngitis, earache in, *Jan.*, 1055
 Lavage, gastric, for diagnosis of tuberculosis, *Nov.*, 721
 Lead neuritis, *Nov.*, 953
 poisoning, abdominal pain in, *March*, 1613
 in children, convulsions from, *July*, 257
 Lentilles, *May*, 1876
 Leprous polyneuritis, *Nov.*, 958
 Leukemia, chronic myelogenous, *Sept.*, 546, 549
 in children, *May*, 1971
 Leukopenia, pernicious, *July*, 103-122
 Leukoplakic vulvitis, *March*, 1446; *May*, 1900, 1910
 Leukorrhea, *Sept.*, 349
 Lichen planus of vulva, *May*, 1899, 1909
 Lipemia, retinal, *Jan.*, 1233
 Liver, active principle, *July*, 49, 75
 storage of, *July*, 57, 58
 disease in children, pain in, *March*, 1611
 extract, intra-osseous injection, in pernicious anemia, *July*, 50
 extrinsic factor, *July*, 49, 51
 functional tests, *Jan.*, 1165
 insufficiency, with jaundice, treatment, *March*, 1651-1657
 therapy in secondary anemias, *July*, 96
 Liver-stomach mixtures in pernicious anemia, *July*, 49
 Lobar pneumonia. See *Pneumonia*.
 Lobectomy for bronchiectasis, *Jan.*, 1175
 Löwenstein's culture medium in tuberculosis, *Nov.*, 722
 Lumbago, relief of, *Jan.*, 1033-1038
- Lumbar puncture in pseudo-uremic convulsions, *July*, 240
 Luminal. See *Phenobarbital*.
 Lung, abscess of, bronchial obstruction in, *Sept.*, 456, 462
 complicating pneumonia, *July*, 33, 34
 carcinoma of, bronchial obstruction in, *Sept.*, 456
 tuberculosis of. See *Tuberculosis, pulmonary*.
 Lupus erythematosus, *May*, 1877, 1878
 of scalp, *Jan.*, 1242
 visceral lesions of, *July*, 333-346
 miliaris disseminatus faciei, *Sept.*, 617
 Lyon's test in gallbladder disease, diagnostic value, *Nov.*, 679
- MACULA lutea, *Jan.*, 1200
 Malarial treatment of rheumatoid arthritis, *March*, 1372
 Malignant hypertension, *July*, 134
 tumors, roentgen treatment, *Sept.*, 598-603
 Malnutrition, treatment, *May*, 1849-1855
 Mantoux tuberculin test, *Nov.*, 703
 March foot, *Jan.*, 1075
 Marmite in pernicious anemia, *July*, 52, 54, 55, 56, 73
 Marschik's approach to parapharyngeal abscess, *Jan.*, 1158
 Massage, prostatic, *Jan.*, 1181, 1184
 Mastoiditis, pain of, relief, *Jan.*, 1044-1047
 Maxillary sinus infection, pain in, *Jan.*, 1062
 McBurney's point symptoms in appendicitis, *July*, 190
 McKhann's placental extract, *March*, 1417
 Measles, immunization, *Nov.*, 734, 735; *Jan.*, 1287; *March*, 1417
 Meckel's diverticulum, *Sept.*, 372, 373
 Mediastinitis, pain in, simulating coronary disease, *Jan.*, 1079
 Memory impairment, menopausal, *July*, 217
 Ménière's syndrome, *March*, 1619
 Meningitis, *Nov.*, 751-769
 Meningococcus antitoxin, *March*, 1423
 Menopause, symptoms and treatment, *July*, 205-226; *March*, 1462
 masking hyperthyroidism, *May*, 1740
 Menorrhagia, menopausal, *July*, 214
 Menstruation, delayed, *March*, 1453

- Mental attitude in inoperable cancer, *July*, 196
 disorders, puerperal, *Nov.*, 927-941
 Mercupurin in heart disease, *March*, 1329
 Mercury polyneuritis, *Nov.*, 955
 Mersalyl in heart disease, *March*, 1329
 Metabolic disturbances in gallbladder disease, *Nov.*, 664
 of pituitary gland, *Nov.*, 832
 Metropathia hemorrhagica, *March*, 1460
 Metrorrhagia, functional, *Sept.*, 359-364; *March*, 1459
 Middle ear disease, pain in, *Jan.*, 1041
 Migraine, relief of, *Jan.*, 1015
 Miliaria crystalline, *May*, 1879, 1880
 Miliary tuberculosis, roentgen findings, *Nov.*, 712
 Milk, evaporated, for infants, *Nov.*, 787
 Mitral stenosis, murmurs of, *March*, 1514
 systolic murmur, *March*, 1507
 Moebius' sign, *Jan.*, 1208
 Molimina, *March*, 1442
 Monilia vaginitis, *March*, 1445
 Moro tuberculin test, *Nov.*, 703
 Mosher's approach to parapharyngeal abscess, *Jan.*, 1158
 Moth, dermatitis due to, *May*, 1883
 Motor education, corrective, in birth injuries, etc., *Nov.*, 800-815
 Mouth care in pneumonia, *July*, 16
 Mucous colitis, *Jan.*, 1123, 1128
 membrane of mouth, atrophy of, *July*, 59
 Mumps, *Nov.*, 736
 immunization, *Jan.*, 1290
 Murmurs, heart, significance and interpretation, *March*, 1505-1518
 Myocardial failure following thyroidectomy, prevention, *May*, 1794
 with hyperthyroidism, *May*, 1726
 Myoma of small intestine, *Sept.*, 371
 Myringotomy, *Jan.*, 1042
 NABOTHIAN cysts, *Sept.*, 349
 Nail, ringworm of, *March*, 1648
 Nausea in acute appendicitis, *July*, 186, 193
 in inoperable cancer, treatment, *July*, 200
 Neck, venous hum in, *March*, 1517
 Neosynthalin as insulin substitute, *Nov.*, 803
 Nephritis, chronic glomerular, complicated, *July*, 171-176
 Nephritis, eye symptoms, *Jan.*, 1235
 in scarlet fever, treatment, *March*, 1396
 Nephroptosis, *May*, 1807
 Nephrosis, amyloid, proteosuria in, *July*, 177-184
 complicating chronic glomerular nephritis, *July*, 171
 Nervous system, intestinal toxemia and, *May*, 1823
 syphilis of, fever therapy, *Sept.*, 590
 vegetative, rôle in climacteric, *July*, 210
 Neufeld reaction for pneumococcus types, Sabin's technic, *July*, 3, 4
 Neuralgia, dental causes, *Jan.*, 1063
 glossopharyngeal, relief of, *Jan.*, 1028
 laryngeal, superior, relief of, *Jan.*, 1029
 occipital, relief of, *Jan.*, 1030
 Sluder's, relief of, *Jan.*, 1031
 trigeminal, relief of, *Jan.*, 1017-1028
 Neurasthenia, traumatic, *Nov.*, 838, 839
 Neurectomy, retrogasserian, for trigeminal neuralgia, *Jan.*, 1028
 Neuritis, multiple. See *Polynuritis*.
 optic, in brain abscess, *Jan.*, 1215
 Neurocirculatory asthenia, *March*, 1534-1545
 masking hyperthyroidism, *May*, 1739
 Neurodermatitis, circumscribed, of vulva, *May*, 1901, 1909
 Neurological manifestations of pernicious anemia, with treatment, *July*, 79-89
 Neuromuscular disease, hyperthyroidism simulating, *May*, 1735
 Neuropsychoses, menopausal, *July*, 216
 puerperal, *Nov.*, 927-941
 Neurosis, cardiac, *March*, 1533
 vertigo due to, *March*, 1620
 Nevi, spider, *Sept.*, 536
 Newborn, hemorrhage of, *May*, 1974
 immunity in, *Nov.*, 733
 Night blindness in gastro-intestinal affections, *Sept.*, 468, 469
 Nipple, bleeding, *March*, 1452
 Nitrites in arterial hypertension, *March*, 1347
 Nitroglycerin in angina pectoris, *Nov.*, 882, 883; *Jan.*, 1099
 Nocturnal indigestion, diagnosis and treatment, *May*, 1797-1806
 Nona, eye symptoms, *Jan.*, 1228
 Nutritional anemia, *July*, 37-77

- OBESITY, pituitary, *Nov.*, 827, 832
 Occipital neuralgia, relief, *Jan.*, 1030
 Ocular vertigo, *March*, 1619
 Onychomycosis, *March*, 1648
 Ophthalmic disorders in hyperthyroidism, *May*, 1736
 test for allergens, *May*, 1921
 Ophthalmoplegia in epidemic encephalitis, *Jan.*, 1228
 Ophthalmoscopic test, *Jan.*, 1198
 Optic disk, *Jan.*, 1200
 neuritis in brain abscess, *Jan.*, 1215
 Organotherapy in pituitary disorders, *Nov.*, 818
 Osteo-arthritis of spine, pain of, simulating angina pectoris, *Jan.*, 1077
 Otagia, *Jan.*, 1039
 Otitis media in scarlet fever, *March*, 1391
 treatment, *March*, 1395
 pain in, relief, *Jan.*, 1041-1048
 Otodynia, *Jan.*, 1039
 Otomycosis, *Jan.*, 1050
 Ovarian factor in menopause, *July*, 205
 hormones in arterial hypertension, *March*, 1353
 urine tests for, *March*, 1440
 Ovarian-pituitary interrelationship, *July*, 206
 Ovulation, *March*, 1447
 Oxygen therapy in congestive heart failure, *March*, 1565
 in pneumonia, *July*, 9-12
 Oxyuris vermicularis infestation of vulva, *May*, 1897, 1909
- PAIN, abdominal, clinical significance and relief, *Jan.*, 1113-1129
 in children, *March*, 1603-1615
 severe, following emotional storm, *Sept.*, 399-402
 in acute appendicitis, *July*, 186, 190
 in cystitis, *May*, 1959
 in dental field, *Jan.*, 1057-1066
 in inoperable cancer, control, *July*, 198
 in pelvic lesions of female, relief, *Jan.*, 1122, 1131
 in peptic ulcer, *Jan.*, 1120, 1126
 in pneumonia, treatment, *July*, 13
 in region of heart, *March*, 1533-1545
 relief of, symposium on, *Jan.*, 1015
 shoulder, in gallbladder disease, *Nov.*, 651
 simulating pain of coronary disease, *Jan.*, 1070-1083
 Painful feet, relief of, *Jan.*, 1060-1075
- Palpitation, menopausal, *July*, 216
 Pancreas, disease of, associated with gallbladder disease, *Nov.*, 664
 Pancreatic ferments, *Nov.*, 683
 Paracentesis, abdominal, in congestive failure, *March*, 1570
 of ear drum, *Jan.*, 1042
 Paraldehyde as soporific, *March*, 1599
 Paralysis, birth, corrective motor education, *Nov.*, 807-815
 infantile. See *Poliomyelitis*.
 jake or ginger, *Nov.*, 953
 Parapharyngeal space infections, *Jan.*, 1152
 Parasites in bile, *Nov.*, 680
 Parental serum in measles, *Nov.*, 735
 Paresthesia, menopausal, *July*, 217
 Paronychia, chronic, *March*, 1647
 Paroxysmal tachycardia, *Nov.*, 857-863; *March*, 1325
 emergency treatment, *May*, 1863
 Parry's disease, eye symptoms, *Jan.*, 1204
 Passive transfer test for allergy, *May*, 1920, 1936
 Patch test in eczema, *July*, 323
 Pediculi, itching due to, *Nov.*, 976
 Pellagra, *July*, 60-62; *March*, 1496
 in gastro-intestinal disease or abnormality, *Sept.*, 468, 470
 vitamin deficiency in, *Sept.*, 478
 Pelvic abscess, gonorrheal, *Nov.*, 921
 inflammatory disease, gonorrheal, *Nov.*, 920
 lesions in female, pain of, relief, *Jan.*, 1122, 1131
 sympathectomy, *Jan.*, 1136
 Pelvimetry, prenatal, *March*, 1661
 Peptic ulcer in children, *March*, 1608
 nocturnal pain in, *May*, 1798
 obstructive, diagnosis and management, *March*, 1519-1524
 pain in, *Jan.*, 1120, 1126
 perforation of, pain in, simulating coronary disease, *Jan.*, 1082
 recurrent, reactivated and anastomotic, *Sept.*, 429-452
 Periapical infection, pain in, *Jan.*, 1059
 Pericardial effusion, emergency treatment, *May*, 1862
 friction rubs, *March*, 1516
 Pericarditis, acute fibrinous, simulating coronary disease, *Jan.*, 1078
 complicating chronic glomerular nephritis, *July*, 171
 constrictive, chronic, *March*, 1336
 uremic, *July*, 238
 Perichondritis, auricular, *Jan.*, 1051
 Peritoneal puncture in pneumococcus peritonitis, *Nov.*, 851, 852

- Peritonitis in children, *March*, 1612
 pneumococcus, *Nov.*, 847, 855
 peritoneal puncture in, *Nov.*, 851, 852
 postoperative, vaccination against, *Sept.*, 620
 Pernicious anemia. See *Anemia, pernicious*.
 leukopenia, *July*, 103-122
 Peroneal sign in tetany, *July*, 255
 Personality, psychopathic, *May*, 1985-1997
